Executive Summary

The KSM Project infrastructure will require an Authorization under Section 35(2) of the *Fisheries Act* to permit the harmful alteration, destruction or disruption (i.e., HADD) of fish habitat. Fish habitat will be lost as a result of dams, road crossing structures and transmission line crossings. In addition, fish habitat will be lost due to the creation of the Tailing Management Facility (TMF). Fish habitat compensation is required and related to the deposit of deleterious substances within fish bearing watercourses of the TMF and seepage collection ponds. Compensation for the loss of fish habitat within the TMF is governed by Section 36(1) of the *Fisheries Act: Metal Mining Effluent Regulations*.

Wetland habitat will be lost due to KSM Project infrastructure. At the request of Environment Canada (A Robinson pers. comm.), a Wetland Compensation Plan for the proposed KSM project is required. This plan will be designed to mitigate the expected loss of wetland functions and habitats associated with the development of the TMF, and meet the expectations of Environment Canada in regards to the *Federal Wetland Conservation Policy* (Environment Canada 1991). Wetland compensation will be integrated within the fish habitat compensation plan(s).

There are two types of habitat compensation projects identified to compensate for the fish habitat loss. The types are: off-channel creation and instream enhancement. There are six off-channel creation projects and four instream enhancement projects currently proposed.

There were a number of objectives for the 2011 KSM Fish and Fish Habitat Compensation Baseline Program. Generally, the objectives were to assess overwintering habitat within identified fish habitat compensation sites; assess steelhead spawning habitat in Oweegee Creek, Gilbert Creek and East Todedada Creek fish habitat compensation sites; assess rearing habitat within instream fish habitat compensation sites; and propose a fish habitat compensation monitoring plan based upon a synthesis of existing data.

For each instream habitat enhancement project, “poor” and “target” reference stream sites were selected to show differences in abundance, condition and growth within and between streams. For each off-channel habitat enhancement project, “poor” treatment wetlands were selected for comparisons with “target” reference wetlands.

For overwintering habitat assessments, wetland mean ice thickness was 0.6 m and the water column had low dissolved oxygen concentrations. No fish were caught in most wetland and stream sites, except at sites with groundwater influence. For steelhead spawning habitat assessment, a total of 72 steelhead redds were detected in Oweegee Creek with greater than 70 individual fish enumerated. Critical steelhead spawning areas were identified downstream of a confined valley wall section. A total of three steelhead redds were detected within Gilbert Creek with a total of four individual fish enumerated.

The results of cumulative mean instream cover (weighted by wetted area) demonstrate that instream cover at poor habitat (run/cascade) sites is consistently 50% lower compared to target habitat (riffle-pool) sites within the same stream. The results of cumulative mean instream cover demonstrate that target habitat provides a greater diversity of cover types.

Stream CPUE data indicates that, although variable, differences in species-specific CPUE between target and poor habitat are apparent. With respect to each gear type, target habitat CPUE is generally higher than poor habitat CPUE, and in certain cases is statistically significant. Furthermore, biomass/density is higher in target habitats than poor habitat because minnow traps must be used in

2011 FISH AND FISH HABITAT COMPENSATION BASELINE REPORT

combination with electrofishing to effectively sample target pool habitats; and parr and sub-adults are more abundant in pool habitat types.

Wetland CPUE data demonstrates that coho salmon (parr) and Dolly Varden (parr and adult) are more abundant in reference wetlands compared to treatment wetlands, except East Todedada Creek Wetland 2.

Acknowledgements

This report was produced by Rescan Environmental Services Ltd. (Rescan). Christopher Burns (B.Sc., R.P.Bio.) was the Rescan Project Manager and author of the report. François Landry (M.Sc., R.P.Bio.) aided in project management. Steve Jennings (B.Sc., R.P.Bio.) provided biological advice. Kerry Marchinko (Ph.D.) assisted statistical design and analysis. The following fisheries staff conducted field work and led field crews: Christopher Burns (B.Sc., R.P.Bio.), Glen Keddie and Mike Stamford (M.Sc.). Field assistance was provided by Jarvis Williams, Vernon Russell and James Morgan. Lakelse Helicopters provided helicopter support. Report production was co-ordinated by Robert Tarbuck (Word Processing), Francine Alford (Graphics) and Pieter van Leuzen (GIS).

TMF	Tailing Management Facility

1. Project Summary

1.1 PROJECT PROPOSER

Seabridge Gold Inc. (Seabridge) is the proponent for the proposed KSM Project (the Project), a gold, copper, silver, molybdenum mine.

1.2 PROJECT LOCATION

The Project is located in the coastal mountains of northwestern British Columbia. It is approximately 950 km northwest of Vancouver and 65 km northwest of Stewart, within 30 km of the British Columbia-Alaska border (Figure 1.2-1).

1.3 PROJECT OVERVIEW

The Project is located in two geographical areas: the Mine Site and Processing and Tailing Management Area (PTMA), connected by twin 23-km tunnels, the Mitchell-Treaty Twinned Tunnels (Figure 1.3-1). The Mine Site is located south of the closed Eskay Creek Mine, within the Mitchell, McTagg, and Sulphurets Creek valleys. Sulphurets Creek is a main tributary of the Unuk River, which flows to the Pacific Ocean. The PTMA is located in the upper tributaries of Teigen and Treaty creeks. Both creeks are tributaries of the Bell-Irving River, which flows to the Nass River and into the Pacific Ocean. The PTMA is located about 19 km southwest of Bell II on Highway 37.

The Mine Site will be accessed by a new road, the Coulter Creek Access Road, which will be built from km 70 on the Eskay Creek Mine Road. This road will follow Coulter and Sulphurets creeks to the Mine Site. The PTMA will also be accessed by a new road, the Treaty Creek Access Road, the first 3-km segment of which is a forest service road off of Highway 37. The Treaty Creek Access Road will parallel Treaty Creek.

Four deposits will be mined at the KSM Project—Kerr, Sulphurets, Mitchell, and Iron Cap—using a combination of open pit and underground mining methods. Waste rock will be stored in engineered rock storage facilities located in the Mitchell and McTagg valleys at the Mine Site. Ore will be crushed and transported through one of the Mitchell-Treaty Twinned Tunnels to the PTMA. This tunnel will also be used to route the electrical power transmission lines. The second tunnel will be used to transport personnel and bulk materials. The Process Plant will process an average of 130,000 tpd of ore to produce a daily average of 1,200 t of concentrate. Tailing will be pumped to the Tailing Management Facility from the Process Plant. Copper concentrate will be trucked from the PTMA along highways 37 and 37A to the Port of Stewart, which is approximately 170 km away via road.

The mine operating life is estimated at 51.5 years. Approximately 1,800 people will be employed annually during the Operation Phase. Project Construction will take about five years, and the capital cost of the Project is approximately US\$5.3 billion.

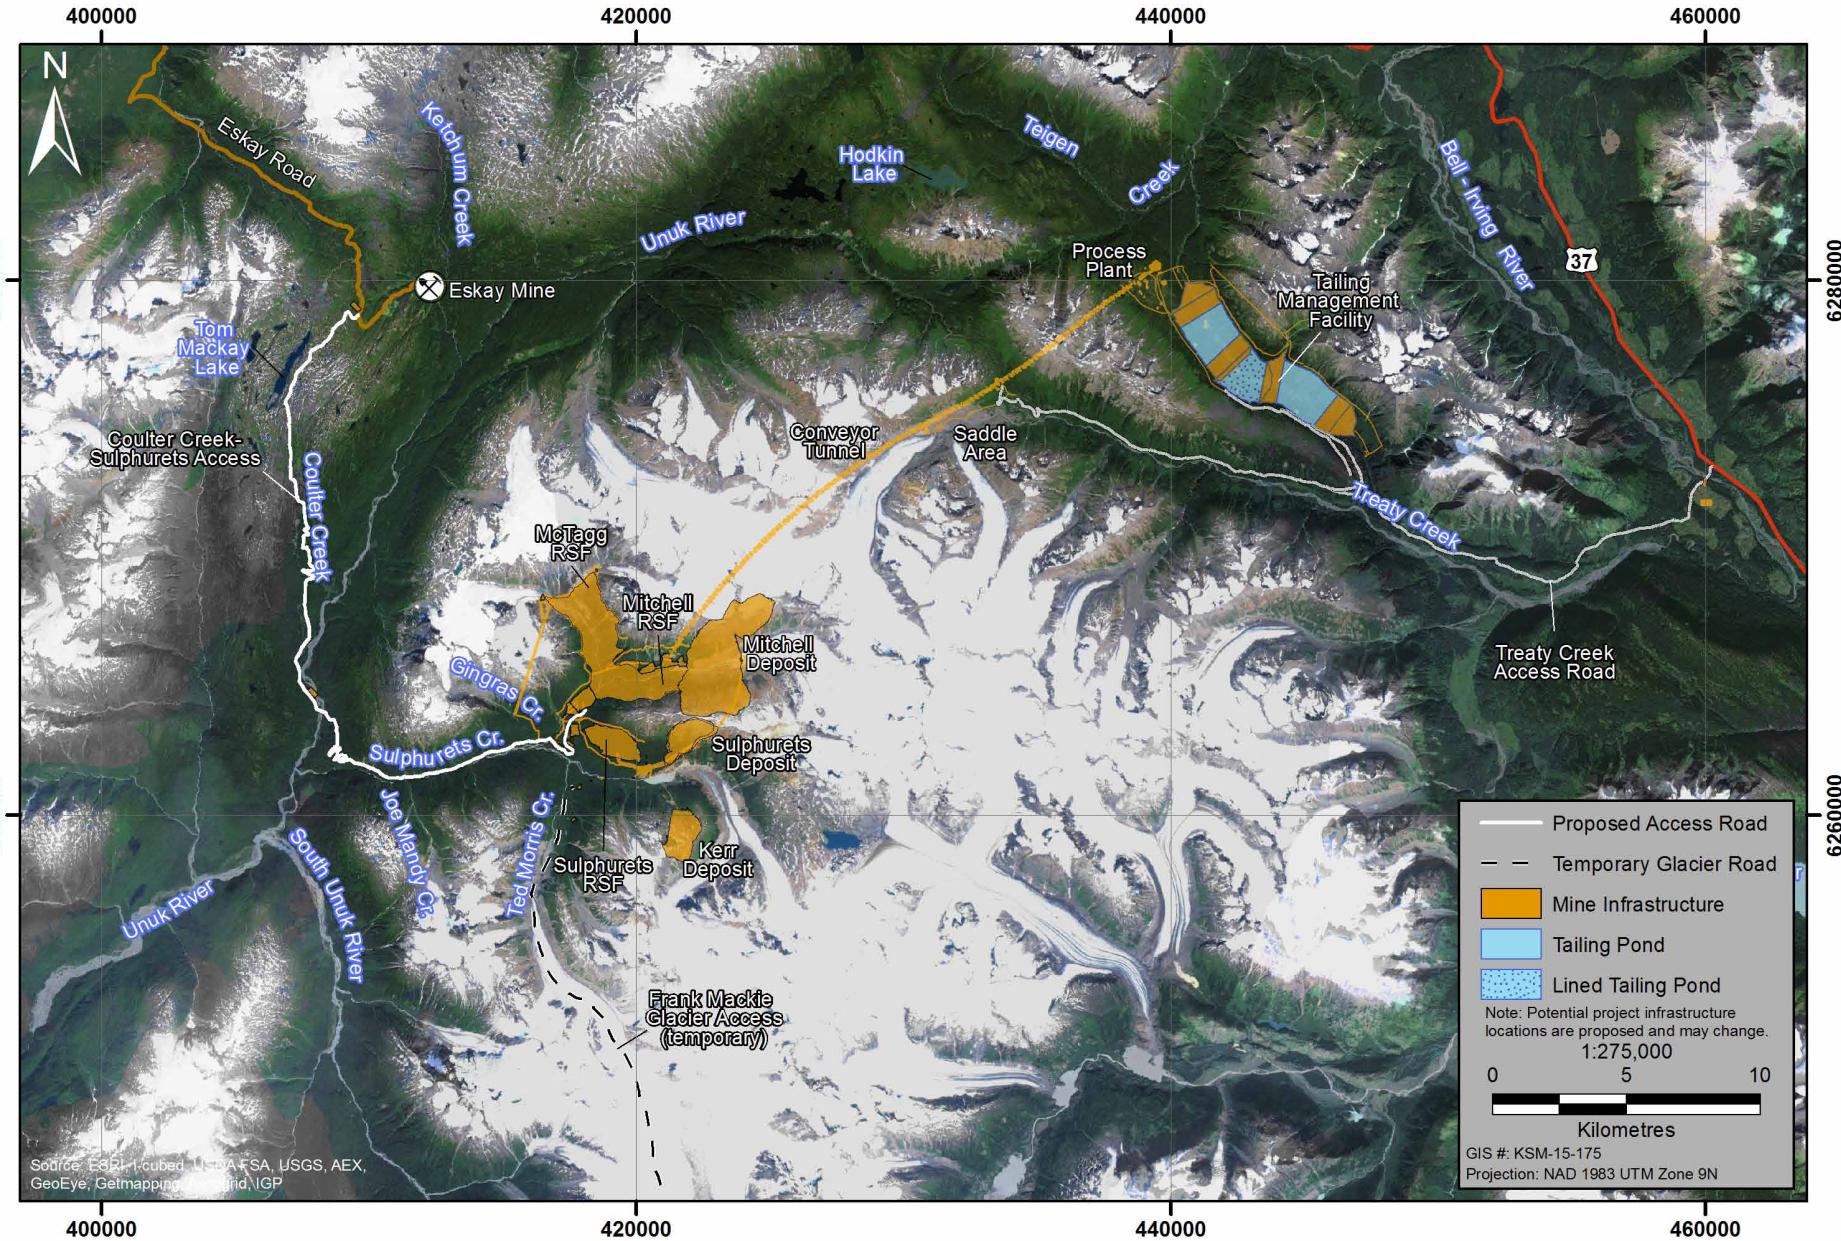

Figure 1.3-1

2. Introduction

2.1 BACKGROUND

The KSM Project infrastructure will require an Authorization under Section 35(2) of the *Fisheries Act* (DFO 1985) to permit the harmful alteration, destruction or disruption (i.e., HADD) of fish habitat. Fish habitat will be lost as a result of dams, road crossing structures and transmission line crossings.

In addition, fish habitat will be lost due to the creation of a TMF. Fish habitat compensation is required and related to the deposit of deleterious substances within fish bearing watercourses of the TMF and seepage collection ponds. Compensation for the loss of fish habitat within the TMF is governed by Section 36(1) of the *Fisheries Act: Metal Mining Effluent Regulations* (MMER).

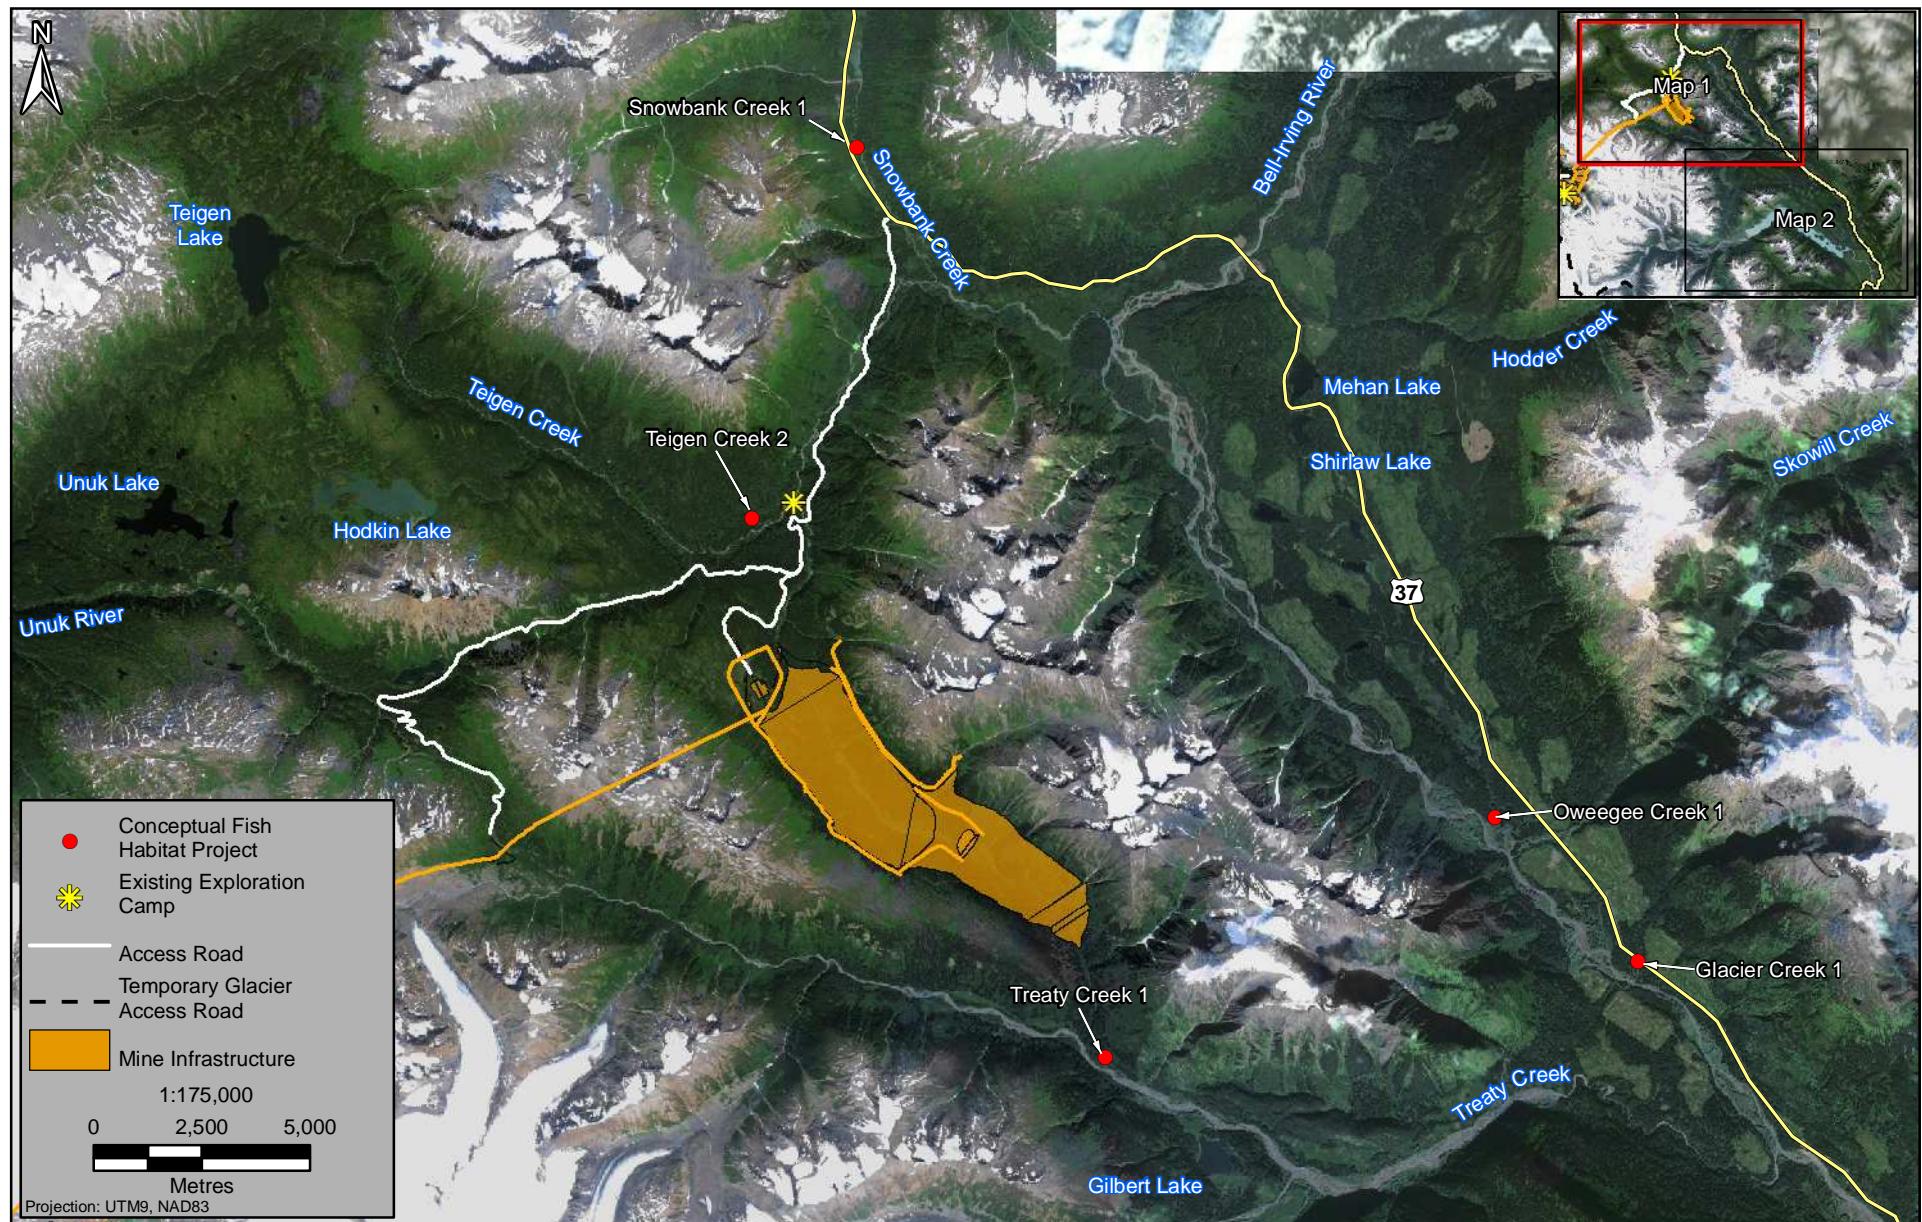

In 2010, desktop analysis and field assessments were conducted to identify a number of conceptual fish habitat compensation projects (Rescan 2011a). Of these conceptual projects, ten were selected for further investigations (i.e., surveying hydrology, engineering) in 2011. The locations of the conceptual projects are presented in Figures 2.1-1 and 2.1-2. The projects are located within seven watersheds. These watersheds include: Teigen, Snowbank, Treaty, Todedada, Glacier, Taft and Oweegee.

Detailed fish and fish habitat assessment data are presented in *KSM Project: 2010 Fisheries Baseline Study Report* (Rescan 2011a) for each compensation project. A summary of fish species and life history stages present at each site is presented in Table 2.1-1. Dolly Varden and coho salmon are the most common species present at the majority of compensation sites. The abundance and distribution of fish at specific compensation sites varies depending upon habitat limitations. Target habitat and species priorities were assigned to each compensation site based upon field assessment data and compensation concept techniques (Table 2.1-2). Target species-specific life history stages were identified for each compensation site.

There are two types of habitat compensation projects identified: off-channel creation and instream enhancement. There are six off-channel creation projects and four instream enhancement projects (Table 2.1-2). Each of these project types are discussed below.

Off-channel habitat is present within and outside of the study area, particularly along the floodplains of Treaty and Teigen creeks, and the Bell-Irving River (Rescan 2010, 2011a). Off-channel habitat includes beaver ponds, side channels, wall-base channels, small tributaries and relic overflow channels along floodplains. Off-channel habitat in the study area is used for summer rearing and overwintering by Dolly Varden and juvenile coho salmon (Rescan 2007, 2009, 2010, 2011a). Off-channel habitats also provide overwintering habitat, which is commonly a limiting factor and a population bottleneck for juvenile salmonids, particularly for coho salmon (Sandercock 1991; Cunjak 1995; Lister and Finnigan 1997; Solazzi et al. 2000). Therefore, the primary biological objective for these conceptual projects is to enhance and create rearing and overwintering habitat in channels, pools and ponds for Dolly Varden and coho salmon.

The biological objectives will be accomplished by constructing ponds, berms, water intakes and small channels along the floodplains of larger streams. New ponds will be excavated or existing ponds deepened and enlarged. Berms will be built to create backwatered ponds connected by small channels. Inlet channels will intercept groundwater and side channels will carry surface water from small tributaries and surface intakes.

Instream enhancement projects involve the creation of pools through the addition of wood, boulders and rock riffles. Pool and cover structures (e.g., wood triangles, log/boulder jams, single logs, opposing v-weirs, rock riffles) will be added to existing channels to improve rearing habitat (Slaney et al. 1997). Wood structures create pools, provide refuge and cover, store and trap sediment, dissipate energy and stabilize channels (Slaney and Martin 1997; Cederholm et al. 1997).

Juvenile salmonids will use the cover and complex shear zones provided by woody debris and boulders in a pool to defend feeding territories. In general, the greater the abundance of cover and pools in a channel, the greater the density of summer rearing and overwintering fish of all life stages (Allan and Lowe 1997; Ward 1997; Slaney and Martin 1997). Fish territory size and preferred depths increase with fish size, hence the deeper and larger a pool becomes, the higher the likelihood it will be used by multiple ages, sizes and species of fish (Keeley et al. 1996). Complex cover within a pool aids juvenile fish in finding refuge from predatory adult fish, each other and peak flows. Adult fish rely upon cover and pools when holding and the tailout sections are commonly used for spawning habitat.

2.2 OBJECTIVES

The overall objective of Fisheries and Oceans Canada's (DFO) *Policy for the Management of Fish Habitat* is to achieve a net gain in the productive capacity of fish habitats (DFO 1986). True gains and losses of habitat are difficult to gauge without clear objectives and structure for biological assessment. To monitor the success of compensation projects rigorous baseline data must be collected to determine the appropriate monitoring method.

There were a number of objectives for the 2011 KSM Fish and Fish Habitat Compensation Baseline Program. The objectives were as follows:

Overwintering Habitat

- determine fish presence, community composition, habitat quality and spatial distribution of overwintering fish habitat within identified fish habitat compensation sites;

Steelhead Spawning Habitat

- determine steelhead spawning habitat distribution and redd abundance in Oweegee Creek, Gilbert Creek and East Todedada Creek fish habitat compensation sites;

Rearing Habitat

- assess the relative abundance, growth and condition of stream rearing salmonids within instream fish habitat compensation sites; and
- assess the relative abundance, growth and condition of wetland rearing Dolly Varden and coho salmon within wetland fish habitat compensation sites.

Table 2.1-1. Species and Life History Stages Present at Compensation Sites

					Species and Life Stage Present

3. Experimental Design

The purpose of site effectiveness monitoring is to effectively monitor the success of fish habitat enhancement works by comparing fish and fish habitat before and after enhancement. Site effectiveness monitoring is used to ensure that a project is meeting quantitative design objectives. The objectives of site effectiveness monitoring are to quantify the net change in habitat productive capacity (Pearson et al. 2005). Considerations for site effectiveness monitoring include: choosing an appropriate experimental design, choosing the appropriate scales for monitoring, identifying factors limiting production in target populations (bottlenecks), controlling for effects of fish movement, recognizing difficulties in measuring the productive capacity of habitat, avoiding cumulative impacts, and dealing with tradeoffs among species (Pearson et al. 2005).

Before data is collected, an experimental design must be established to address the hypotheses being tested, to anticipate any problems in data collection and to ensure the assumptions underlying statistical tests are met. As recommended by Pearson et al. (2005), a Paired Before-After Control-Impact (BACIP) experimental design was used for this study. It is also the simplest spatially-nested design, with controls at two scales (“local” and “distant”). Local and distant reference sites allows for spatial nesting to permit examination of fish movement effects on local abundance and provides insurance in case of problems with one reference site.

Currently, there are two types of conceptual fish habitat compensation projects proposed (Table 2.1-1). The types are:

- off-channel habitat creation; and
- instream habitat enhancement.

Reference and treatment streams were selected to compare fish abundance between streams, since we are concerned with relative difference between streams. A reference stream represents the conditions one is trying to achieve with the instream habitat enhancement (Roni 2005). A treatment stream represents the stream in which instream habitat enhancement is proposed.

For each instream habitat enhancement project, “poor” and “target” sites were selected to show differences in fish abundance within and between streams (Table 3.1-1). Poor stream sites represent habitat units that have a low productive capacity (i.e., run or cascade habitat units) that would benefit from instream enhancement to increase productive capacity. Target reference stream sites represent habitat units that have a high productive capacity (i.e., pool habitat units) and serve as a reference one is trying to achieve with instream enhancement.

For instream habitat enhancement projects, the analysis is focused on site-level response, not reach-level response to fish abundance (Roni 2005). Inferences about reach-level response can be made post-construction, since sites will be randomly selected.

For each off-channel habitat enhancement project, “poor” treatment wetlands were selected for comparisons with “target” reference wetlands (Table 3.1-2).

Target reference sites were selected to be similar in character to treatment sites, but not assumed to be identical to treatment sites. However, minimizing differences is likely to increase a study’s power to detect change (Pearson et al. 2005).

2011 FISH AND FISH HABITAT COMPENSATION BASELINE REPORT

Table 3.1-1. Instream Habitat Enhancement Project Site Types

Watershed	Watercourse	Site Number	Reference Stream Sites	
			Local (Target and Poor Habitat)	Distant (Target Habitat)
Oweegee	Oweegee Creek	1	Oweegee Creek - Lower	Oweegee Creek - Upper, Gilbert Creek, Snowbank Creek - Trib
Snowbank	Snowbank Creek	1	Snowbank Creek*	Teigen Creek
Todedada	East Todedada Creek	1	East Todedada Creek - Upper	Oweegee Creek - Upper, Gilbert Creek, Snowbank Creek - Trib
Todedada	East Todedada Creek	3	East Todedada Creek - Lower	Oweegee Creek - Upper, Gilbert Creek, Snowbank Creek - Trib

*Only poor habitat present

Local = Sites located within the same reach

Distant = Sites located within an upstream reach or different watershed

Table 3.1-2. Off-Channel Habitat Creation Project Site Types

Watershed	Watercourse	Site Number	Treatment Wetlands (Poor Habitat)	Reference Wetlands (Target Habitat)
Glacier	Glacier Creek	1	NA	Treaty Wetlands 1, 2, 3 and 7
Taft	Taft Creek	1	NA	Oweegee Wetland 1
Taft	Taft Creek	2	Taft Compensation Wetlands 1 and 2	Teigen Wetland 4, 5, 6, 8, 9
Teigen	Teigen Creek	2	Treaty Compensation Wetlands 1, 2 and 3	
Todedada	East Todedada Creek	2	Todedada Wetland 1 and 2*	
Treaty	Treaty Creek	1	Treaty Compensation Wetlands 1 and 2

4. Methods

4.1 OVERWINTERING HABITAT ASSESSMENT

4.1.1 Fish Habitat

Each overwintering stream/side channel pool habitat site and wetland site was located in the field based upon the previous field seasons site assessment data (Rescan 2011a). Sample locations for overwintering habitat assessment are shown in Table 4.1-1. The timing of this assessment occurred from March 7 to 15, 2011.

Table 4.1-1. Sample Locations for Overwintering Habitat Assessment

Habitat Type	Location
Stream (pool)	Taft Creek
	Glacier Creek
	Oweegee Creek
	East Todedada Creek
	Snowbank Creek
Side Channel (pool)	Oweegee/Bell-Irving
	Teigen Creek
Wetland	East Todedada
	Teigen Creek 2
	Treaty Creek 1
	Treaty Creek Reference

For each wetland and stream/side channel pool habitat site, snow and ice thickness was measured (to the nearest 1 cm) with a tape measure and/or measuring ruler. Water depth was measured (to the nearest 1 cm) with a measuring ruler. Dissolved oxygen (mg/L) was measured with an YSI Meter.

4.1.2 Fish Community and Biology

Fish were sampled using baited minnow traps in each stream/side channel pool and wetland under the ice. Minnow traps were 42 cm long, 23 cm in diameter, constructed of galvanized metal with 6.3 mm mesh size, and possessed a 2 cm diameter opening. Each minnow trap was baited with one roe mesh bag (approximately 10 g in weight) and set overnight.

Single haul minnow trapping CPUE was calculated as an index of relative abundance for all life history stages. All fish captured were placed immediately in a holding tank for biological processing. Captured fish were identified to species and counted. Fork length was measured (to the nearest 1 mm) for all fish captured.

4.2 STEELHEAD SPAWNING ASSESSMENT

Steelhead snorkel/redd surveys were conducted within Oweegee Creek (downstream of the lake), East Todedada Creek and Gilbert Creek to: confirm steelhead spawning presence, determine steelhead spawning habitat distribution throughout the creek, determine timing of steelhead spawning, and provide an index of adult abundance. The timing of this assessment occurred from May 26 to 28, 2011.

Snorkel/redd survey methods followed those detailed in Johnston et al. (2007). Snorkel surveys were conducted with two snorkelers with previous experience conducting steelhead enumeration and redd surveys to develop a consistent application of redd identification. The following data were collected for each snorkel survey: survey date, start and end UTM, start and end time, water clarity (turbid, lightly turbid, moderately turbid, clear), horizontal visibility (m), weather (cloudy, partly cloudy, sunny), water and air temperature ($^{\circ}\text{C}$), and precipitation (heavy rain, light rain, no rain). Horizontal visibility was measured by one snorkeler holding a black object in the water column, and another snorkeler measured the upstream distance at which he/she could longer see the object in the water column.

All steelhead observed were enumerated. All redds were identified, measured, flagged and georeferenced. Each redd was assigned a unique number. The number of fish on a redd was recorded, if present. Redd longevity and observer efficiency in redd detection were estimated by tracking the condition of individual redds measured during repeated surveys, if conducted (Gallagher and Gallagher 2005). Each redd was classified as one of the following for each site visit:

1. new since last survey but still clear;
2. still measurable but already measured;
3. no longer measurable but still apparent;
4. no redd apparent, only a flag; and
5. poor conditions; cannot determine if present and measurable or not.

4.3 STREAM SUMMER REARING ASSESSMENT

4.3.1 Site Selection

Consistent application of site selection criteria can reduce the variability of non-normally distributed fish abundance data (Hankin 1984). Due to channel complexity and variable instream cover throughout the reach, standard site lengths were not selected. Site length varied to encompass entire habitat units (riffle, pool, glide, run, cascade) to reduce variability of abundance data.

Target habitat sites (i.e., target habitat to create through instream enhancement) were identified based upon representative riffle-pool habitat unit complexes. Poor habitat sites (i.e., habitat to alter with instream enhancement) were identified based upon representative run or cascade habitat units. All site boundaries commenced at a thalweg crossover point, included one crossover point, and ended at a crossover point. A crossover point is where the stream thalweg is in the centre of the channel during bankfull discharge (Stanfield 2005). Each identified site was assigned a unique number and a sub-sample of sites was selected for assessment with the use of a random number generator from MS Excel.

4.3.2 Fish Habitat

Detailed fish habitat assessments (FHAP) were conducted at all sites to compare channel complexity and instream cover, and to calculate site length (m) and area (m^2) (Johnston and Slaney 1996). At each site, UTM coordinates were recorded with a GPS unit. Temperature ($^{\circ}\text{C}$), pH, and conductivity ($\mu\text{S}/\text{cm}$) were recorded using electronic meters.

FHAP assessments involved differentiating the stream into separate habitat units such as riffles, runs, cascades, glides and pools, and then recording an array of habitat attributes for each unit. These attributes included data on substrate composition, cover for fish and fish habitat type. A complete list of the attributes measured is presented in Table 4.3-1. Data were collected with a measuring tape,

metre stick, or visual estimation. Stream habitats within these sites were separated into the following habitat units:

- pool - low velocity area with smooth, non-turbulent flow, low gradient (near 0%), and a concave bottom;
- glide - an area of smooth, non-turbulent flowing water with moderate velocity and gradient less than 3%;
- riffle - an area of turbulent, fast-flowing water with a gradient less than 3%;
- run - an area of low turbulence, fast-flowing water with a gradient less than 3%; and
- cascade - high gradient (> 3%) area of turbulent, fast-flowing water.

Table 4.3-1. FHAP Attributes Assessed and Measured at Stream Sites

Habitat Type	Substrate Type	Physical Measurements	Habitat	Cover
% Pool	% Sand	Length (m)	Pool Type	% Deep Pool
% Riffle	% Gravel	Wetted Depth (m)	Pool Residual Depth (m)	% Boulder
% Glide	% Cobble	Bankfull Depth (m)	Fish Passage Barriers	% Instream Vegetation
% Cascade	% Boulder	Wetted Width (m)	Off Channel Type	% Overhanging Vegetation
% Run	% Bedrock	Bankfull Width (m)	Islands/Bars	% Undercut Bank
		Gradient (%)	Functional LWD Size Distribution	% LWD
		Bank Height (m)		% SWD
		Temperature (°C)		
		pH		
		Conductivity ($\mu\text{S}/\text{cm}$)		

4.3.3 Fish Community

4.3.3.1 Single Pass Electrofishing

Each site was located and flagged in the field. Electrofishing methods followed those detailed in Johnston et al. (2007). Single pass electrofishing was conducted as an index of abundance. Backpack electrofishing (i.e., Smith-Root LR-24) was conducted within each site by one crew leader and one dip netter. Block nets were not used in single pass electrofishing. Anode ring diameter was 28 cm and dip net diameter was 21 cm with 3.2 mm mesh size. A systematic sweep sampling approach was conducted at each site, in which the entire wetted width was sampled from the downstream to the upstream site boundary (Stanfield 2005). Electrofisher voltage (V), duty cycle (%) and frequency (Hz) settings were consistent between sites in each stream.

Single pass electrofishing catch-per-unit-effort (CPUE) was calculated as an index of relative abundance for all life history stages. The assumptions of the assessment were that (Johnson et al. 2007):

- no fish movement in/out of site during the assessment;
- rate of fish catch is proportional to abundance; and
- capture efficiency is independent of field conditions within each creek.

All fish captured were placed immediately in a holding tank for biological processing.

4.3.3.2 *Mark-Recapture Electrofishing*

Each site was located and flagged in the field. Mark-recapture electrofishing was conducted to calibrate index of abundance estimates for East Todedada Creek. The same methods were applied as single pass electrofishing with key differences (Johnston et al. 2007). Block nets (6.3 mm mesh size) were erected at the upstream and downstream boundaries of the site perpendicular to the flow of the water. Block nets were stretched across the stream channel. Small rocks were used to secure the bottom of the net to the streambed. Once the net was secured along the stream channel, the ends were secured to standing timber using ropes. Block nets were erected instream with bipods to reduce drag created by the current (Plate 4.3-1).

Plate 4.3-1. Block net and bipods set perpendicular to the current in East Todedada Creek.

All fish captured were placed immediately in a holding tank for biological processing. For all captured fish, the pelvic fin was notched to identify marked fish. Fish were not anaesthetized due to mortality associated with this procedure and unknown behavioural effects (Skalski et al. 2009). Clipped fish were monitored for recovery. Fish mortalities were not released, and deceased fish were accounted for in the final estimate. Marked fish were released close to their point of capture by subdividing the site into 10 m sections facilitating returning fish close to their capture point.

The site was resampled 24 hours after the first sampling event and recorded the number of fish by species, their sizes (fork length and weight), and whether the fish was marked. During the recapture event, the same method and level of effort applied as the first pass to ensure that detection probabilities at mark-recapture sites would be consistent. Block nets were then removed.

The assumptions of the closed model mark-recapture assessment were that (Johnson et al. 2007):

- no net movement of fish into or out of the study site;

- fish do not lose their marks during the course of sampling;
- marked and unmarked fish are equally catchable; and
- captured fish are reported correctly as marked or unmarked.

4.3.3.3 Minnow Trapping

Each pool habitat site was located and flagged in the field. Fish were sampled using baited minnow traps in each pool habitat type. Two traps were used in all stream site pools, except five traps were used in pools for Teigen Creek. Each trap was 42 cm long, 23 cm in diameter, constructed of galvanized metal with 6.3 mm mesh size, and possessed a 2 cm diameter opening. Each minnow trap was baited with one roe mesh bag (approximately 10 g in weight) and set for a minimum of 24 h. If a pool was previously electrofished, then a minimum wait time of 24 h was used before setting minnow traps so that fish could redistribute into their preferred habitats and resume normal behavioural patterns.

Single haul minnow trapping CPUE was calculated as an index of relative abundance for all life history stages. The assumptions of the assessment were the same as previously stated for electrofishing; in addition to:

- one minnow trap does not influence the effort and catch of another trap.

All fish captured were placed immediately in a holding tank for biological processing.

4.3.4 Fish Biology

Fish captured were identified to species and counted. Fork length was measured (to the nearest 1 mm) for all fish captured. Life history stages (fry, parr, adult) for fish captured were estimated based upon an analysis of length frequency histograms generated from both the electrofishing and minnow trap data (Section 5.3). Wet weight (to the nearest 0.01 g) with an Ohaus 200 g scale was collected from all fish captured. The first two leading pelvic fin rays were collected from Dolly Varden and rainbow trout for age structure analysis. A maximum of 30 individuals (> 85 mm fork length) were sampled from each stream and wetland.

4.4 WETLAND SUMMER REARING ASSESSMENT

4.4.1 Site Selection

Treatment wetlands were selected as they will be altered according to the conceptual plans of the compensation project. Reference wetlands were selected based upon a number of criteria. The criteria were as follows:

- direct connection to a fish bearing watercourse;
- no barriers to fish movement;
- similar size of wetlands/ponds to be constructed;
- similar depth of wetlands/ponds to be constructed; and
- same species composition of wetlands/ponds to be constructed.

Both treatment and reference wetlands were sampled for summer rearing assessments.

4.4.2 Fish Habitat

Open water wetland habitat was qualitatively described and connectivity to mainstem creeks was documented. The width and length of open water wetland habitats were measured with a handheld range finder (m), maximum water depth (m) was measured, amount of cover and dominant cover type were recorded.

4.4.3 Fish Community and Biology

Each wetland site was located in the field. The fish were sampled using baited minnow traps in each wetland. Five traps were used in all wetland sites. Each trap was 42 cm long, 23 cm in diameter, constructed of galvanized metal with 6.3 mm mesh size, and possessed a 2 cm diameter opening. Each minnow trap was baited with one roe mesh bag (approximately 10 g in weight) and set for a minimum of 24 h.

Fish caught were processed in a standardized manner as discussed in Section 4.3.4.

4.5 AGE STRUCTURE ASSESSMENT

4.5.1 Sample Processing

Fin rays were aged by Stamford Environmental (Gibsons, British Columbia). Individual fin rays were carefully removed from their envelopes, set into epoxi (Koch and Quist 2007) and transverse cross-sections were removed using a low speed saw (Isomet, Beuler Inc.). At least three sections (approximately 0.5 mm thick) were removed, fixed onto a labelled slide and polished with wet-dry sand paper. As they were being mounted, the sections were assessed under a microscope to ensure sufficient information was removed for aging (based on shape of the hemisegments; Ferrierra et al. 1999). Sections were fixed sequentially from left to right on a slide beginning with the most proximal section to enable readers to observe changes to annuli in more distal sections. This is useful for identifying loss of first or second annuli on fin rays that were clipped more distally in the field.

The larger ventral hemisection from the principle fin ray was the primary focus since the second and third fin rays were sometimes insufficiently proximal or absent in some samples. Cross section shape was noted; since this identifies proximal to distal locations along the fin rays and first or second annuli can be lost in distal sections. Round or short tailed comma sections are more proximal, for instance, than long tailed comma or rod shaped sections (Ferrierra et al. 1999). Sometimes more distal sections display better annulus definition; however winter growth can be clouded over by surrounding summer growth in more proximal sections. Consequently, annulus counts for the fish were determined using all information present on the slide, including all sections and any or all of the first three fin rays present in the sample.

4.5.2 Ageing Determination and Precision

Aging precision depended on collecting two independent counts for each fish. Fin ray cross sections were examined independently two times (i.e., no knowledge of the previous age) by the same reader. The coefficient of variation (CV), a measure of variance, was calculated between each read and a final age was assigned to each fin ray structure.

5. Data Analysis

5.1 CPUE

CPUE is an index of relative abundance that can be used to compare fish populations among different areas. It is defined as the number of fish captured per sampling device per unit time.

For electrofishing, the CPUE was calculated from the number of fish captured per 100 seconds:

$$CPUE = \text{number of fish caught} \times (100/\text{electrofishing effort (s)})$$

For minnow traps, CPUE was calculated from the number of fish captured per trap per day (24 h).

$$CPUE = \text{number of fish caught per trap} \times (24 \text{ h/day/set time (h)})$$

CPUE was calculated for each species and by life history stage (i.e., fry, parr, adult and combined).

5.2 POPULATION ESTIMATE

Population estimates were derived from mark-recapture studies. The Schnabel method was used to estimate population size by fish species because multiple marking and recapture samples were collected over a short period, and the sample size was low (Schnabel 1938; Seber 1982; Guy and Brown 2007). The iterative formula to calculate population estimates was:

$$\hat{N} = \frac{\sum_{i=2}^t n_i M_i}{\sum_{i=2}^t m_i + 1}$$

Where t = number of sampling occasions; n_i = number of fish caught in i^{th} sample; m_i = number of fish with marks caught in i^{th} sample; and M_i = number of marked fish present in the population of i^{th} sample.

The variance of the population estimate was calculated using the following:

$$V(\hat{N}) = \hat{N}^2 \left[\frac{\hat{N}}{\sum n_i M_i} + 2. \frac{\hat{N}^2}{(\sum n_i M_i)^2} + 6. \frac{\hat{N}^3}{(\sum n_i M_i)^3} \right]$$

Confidence intervals (95%) for \hat{N} were then calculated.

5.3 LENGTH FREQUENCY

Life history stages (fry, parr, adult) for fish captured were estimated based on an analysis of length frequency histograms generated from both the electrofishing and minnow trap data, as well as from previous fish length and scale data from the Project Area (Rescan 2009, 2010, 2011a). In general, plotted histograms for lengths were reviewed to show clear length-frequency “cut-offs” between age-0 fry and age-1 parr.

Table 5.3-1 shows selected species-specific size ranges assigned to each life history stage.

Table 5.3-1. Species-Specific Fork Length Size Range

Species	Fork Length Size Range (mm)		
	Fry	Parr	Adult*
Chinook Salmon	40 - 80	> 81	NA
Coho Salmon	25 - 65	> 66	NA
Dolly Varden	25 - 50	51 - 90	> 91
Rainbow trout	30 - 65	66 - 105	> 106

NA = sample method not applicable

* Any fish older than parr, not necessarily sexually mature

5.4 CONDITION AND GROWTH

Condition is an index of the relative health of fish (Guy and Brown 2007). It was calculated for all fish for which length and weight data were obtained, and was based on the following formula from Ricker (1975):

$$\text{Condition} = \frac{\text{weight (g)} \times 10^5}{\text{fork length (mm)}^3}$$

Growth models (Ricker 1975) were fit to length-age data using two von Bertalanffy models using a non-linear regression function in R (Version 2.14.1). The equation for the von Bertalanffy model is:

$$l_t = L_\infty(1 - \exp^{-K(t-t_0)})$$

where l_t is the length (mm) at age t (years), L_∞ is the length (mm) that the fish would attain if it were allowed to grow for an infinitely long time, K is a growth coefficient (year -1), and t_0 is the age (years) at zero length.

The alternative von Bertalanffy model (two-parameter model) was used, in which t_0 is fixed at 0, to fit length-age data. The third model used was a linear regression length-age model. All three models were compared to determine which model fits the data best (using the Akaike Information Criterion) and thus providing the best estimate of asymptotic length (L_∞) and growth coefficient (K). The Akaike weights show the magnitude of support for each model (scaled between 0 and 1); the model with the highest weight is the best fit model of three models being compared.

5.5 DESCRIPTIVE STATISTICS

Each data set was examined for data entry errors and outliers through the use of box plots using SYSTAT statistics software (SYSTAT 2004). Obvious outliers were reviewed and removed, if applicable. Descriptive statistics were calculated for habitat, biological and CPUE data. Sample size, standard mean, standard deviation (SD) of the mean, standard error (SE) of the mean, and 95% confidence limits (upper and lower) were calculated for all biological and CPUE data.

A non-parametric bootstrap procedure was used to derive means and percentile bootstrap +/-95% confidence intervals (CI) for biological and CPUE (fry, parr, adult and combined) data for comparisons with standard mean values. Bootstrapping is a computer-based method for assigning measures of accuracy to sample means and is useful when the sample size is insufficient or non-normally distributed for straightforward statistical inference (Hubert and Fabrizio 2007). Bootstrapping was accomplished using 10,000 resamples from the repeated sampling of the actual data rather than a theoretical probability distribution to quantify uncertainty in means (Efron and Tibshirani 1993). Upper and lower

95% confidence limits for the mean from the cumulative distribution of the 10,000 bootstrap iterations (Efron and Tibshirani 1993). Bootstrap iterations were computed using an algorithm written in R (Version 2.14.1), an open-source statistical and programming software package.

5.6 STATISTICAL ANALYSIS

SYSTAT statistics software (SYSTAT 2004) was used for all statistical analyses. Data outlier tests were employed to look for abnormal data through the use of box plots. Normal probability plots and Anderson-Darling tests were employed to test for normality among variables. Levene's test were employed to test for homogeneity of variances. Data were transformed with natural logarithms to meet assumptions of normality, if applicable.

Analyses of variance (ANOVA) were used to test for differences among means. Where transformation of data failed to meet assumptions of a parametric ANOVA, a non-parametric Kruskal-Wallis test was used. Following significant ANOVA or Kruskal-Wallis, pairwise multiple comparisons were performed using Tukey's test and a non-parametric multiple comparison method (Siegel and Castellan 1988). Results of statistical tests and regressions were considered significant if the probability (P) of a false significant result was less than 5% (i.e., $P < 0.05$). Results of all regression analyses were reported with a coefficient of determination (r^2) that was adjusted for the number of degrees of freedom.

6. Quality Assurance and Control

In order to ensure consistently accurate data collection, a Quality Assurance (QA) and Quality Control (QC) program was established at the onset of the field program. The program involved a practice session held in the field prior to any crew conducting stream and wetland assessments to review data collection procedures. Throughout the course of the field program, a qualified and experienced Quality Assurance Biologist reviewed each completed data card daily. A QA checklist was also completed for each site. Whenever clarification was required on specific points, the card was returned to the crew leader for editing and was accepted only after the necessary changes were made.

Data entry into the provincial Field Data Inventory System (FDIS) and other databases, subsequent to the field program, provided another opportunity to ensure data consistency through application of the built-in quality assurance routine which generated a QA report for review. Comments were provided to address deficiencies and conflicts identified in the quality assurance report generated by FDIS. Data transcription quality was also verified by comparing a sub-sample of randomly selected site cards with the corresponding data entered into FDIS and into project maps. The standard for QC under the *Reconnaissance (1:20,000) Fish and Fish Habitat Inventory Protocol* is to verify 5% of all site cards (RISC 2001). Each data set was examined for data entry errors and outliers through the use of box blots using SYSTAT statistics software (SYSTAT 2004). Obvious outliers were reviewed and removed, if applicable.

7. Results and Discussion

7.1 OVERWINTERING HABITAT ASSESSMENT

Appendix 7.1-1 shows all minnow trap set location data for overwintering habitat assessments. Appendix 7.1.2 shows minnow trap effort and catch data. Appendix 7.1-3 shows species biological data for compensation sites. From March 7 to 15, 2011, minnow traps were set within stream/side channel pools and wetland habitats to determine overwintering habitat utilization. Minnow traps could not be set in East Todedada Creek wetland because ice depth was greater than the ice auger length (> 2 m).

Within Treaty Creek 1 compensation project, the deepest wetlands were sampled because previous overwintering assessments indicated that shallow wetlands were frozen to the bottom (Rescan 2010) (Plate 7.1-1). Mean ice thickness was 0.6 m and mean water depth was 0.5 m. No fish were caught and dissolved oxygen concentrations were low (2.5 mg/L). Open water was present in the eastern half of the compensation site with mean water depths of 0.1 cm. The open water was likely due to groundwater influence from adjacent unnamed creek on the eastern end of the site.

A reference wetland was selected in Treaty Creek for comparisons of ice depth, dissolved oxygen concentrations and fish habitat utilization. The reference wetland is located a couple kilometres downstream of the Treaty Creek 1 compensation project. Ice thickness, mean water depth and dissolved oxygen concentrations were similar to that of Treaty Creek 1. In addition, no fish were caught in the reference site.

Within Teigen Creek 2, the largest pond was frozen to the bottom; which is consistent with previous winter assessments (Rescan 2010). The smaller wetlands near the eastern end of the site were ice-free suggesting groundwater influence; which is consistent with previous winter assessments (Plate 7.1-2). Coho salmon parr were caught in the wetlands. The side channel associated with Teigen Creek 2 was ice free. Adequate water depths and flow were present within side channel for overwintering fish. Rainbow trout and coho salmon parr were caught in the side channel.

Within Taft, Glacier, East Todedada Creek, Snowbank and Oweegee creeks; pool habitats were sampled (Plates 7.1-1 to 7.1-6). Adequate water depths and flow were present within each mainstem for overwintering fish. Dolly Varden and coho salmon parr were caught in East Todedada Creek; however, no fish were caught in all other creeks.

The Oweegee Creek/Bell-Irving River side channel was sampled (Plate 7.1-7); in which rainbow trout and coho salmon parr were caught.

7.2 STEELHEAD SPAWNING ASSESSMENT

From May 26 to 28, steelhead redds were detected in Oweegee and Gilbert Creeks (Appendices 7.2-1 and 7.2-2). A total of 72 steelhead redds were detected in Oweegee Creek with greater than 70 individual fish enumerated. A total of three steelhead redds were detected within Gilbert Creek with a total of four individual fish enumerated. Figures 7.2-1 and 7.2-2 show the distribution and density of steelhead redds in Oweegee and Gilbert creeks, respectively. Furthermore, numerous resident rainbow trout were observed spawning in Gilbert Creek, upstream of the first beaver dam.

Hydrological data indicate that freshet typically commences in late May and early June (Rescan 2011b). Discharge (Q) and horizontal visibility (HV) are important determinants of snorkeler detection probability (Korman et al. 2007). Horizontal visibility tends to decline with increasing discharge. At the

time of the assessment, the wetted width was at or just below bankfull height and horizontal visibility was good (i.e., clear) in the Oweegee and Gilbert lake headed watersheds. Adult steelhead were detected holding over or within the vicinity of redds, and the majority of fish showed signs of redd construction (e.g., battered caudal fin). All of this data suggests that the timing of the survey was just past the peak spawning period.

RescanTM
Engineers & Scientists

Within Oweegee Creek, steelhead utilized micro habitats of gravel tight to the banks (Plate 7.2-1). Certain redds were scoured to clay substrates suggesting lack of gravel supply, which is typical of lake headed watersheds (Bison et al. 2006). Steelhead redds were distributed throughout the lower reach; however, the critical spawning area is immediately downstream of a confined valley wall (Figure 7.1-1; Plate 7.2-2).

Plate 7.2-1. Steelhead Redd adjacent to Oweegee Creek Bank.

Plate 7.2-2. Critical steelhead spawning habitat in Oweegee Creek.

No steelhead redds were detected within East Todedada Creek. The lack of steelhead or redd detection in East Todedada Creek was not surprising given that steelhead fry, parr, or adults have not been captured in the creek.

7.3 STREAMS

7.3.1 Fish Habitat

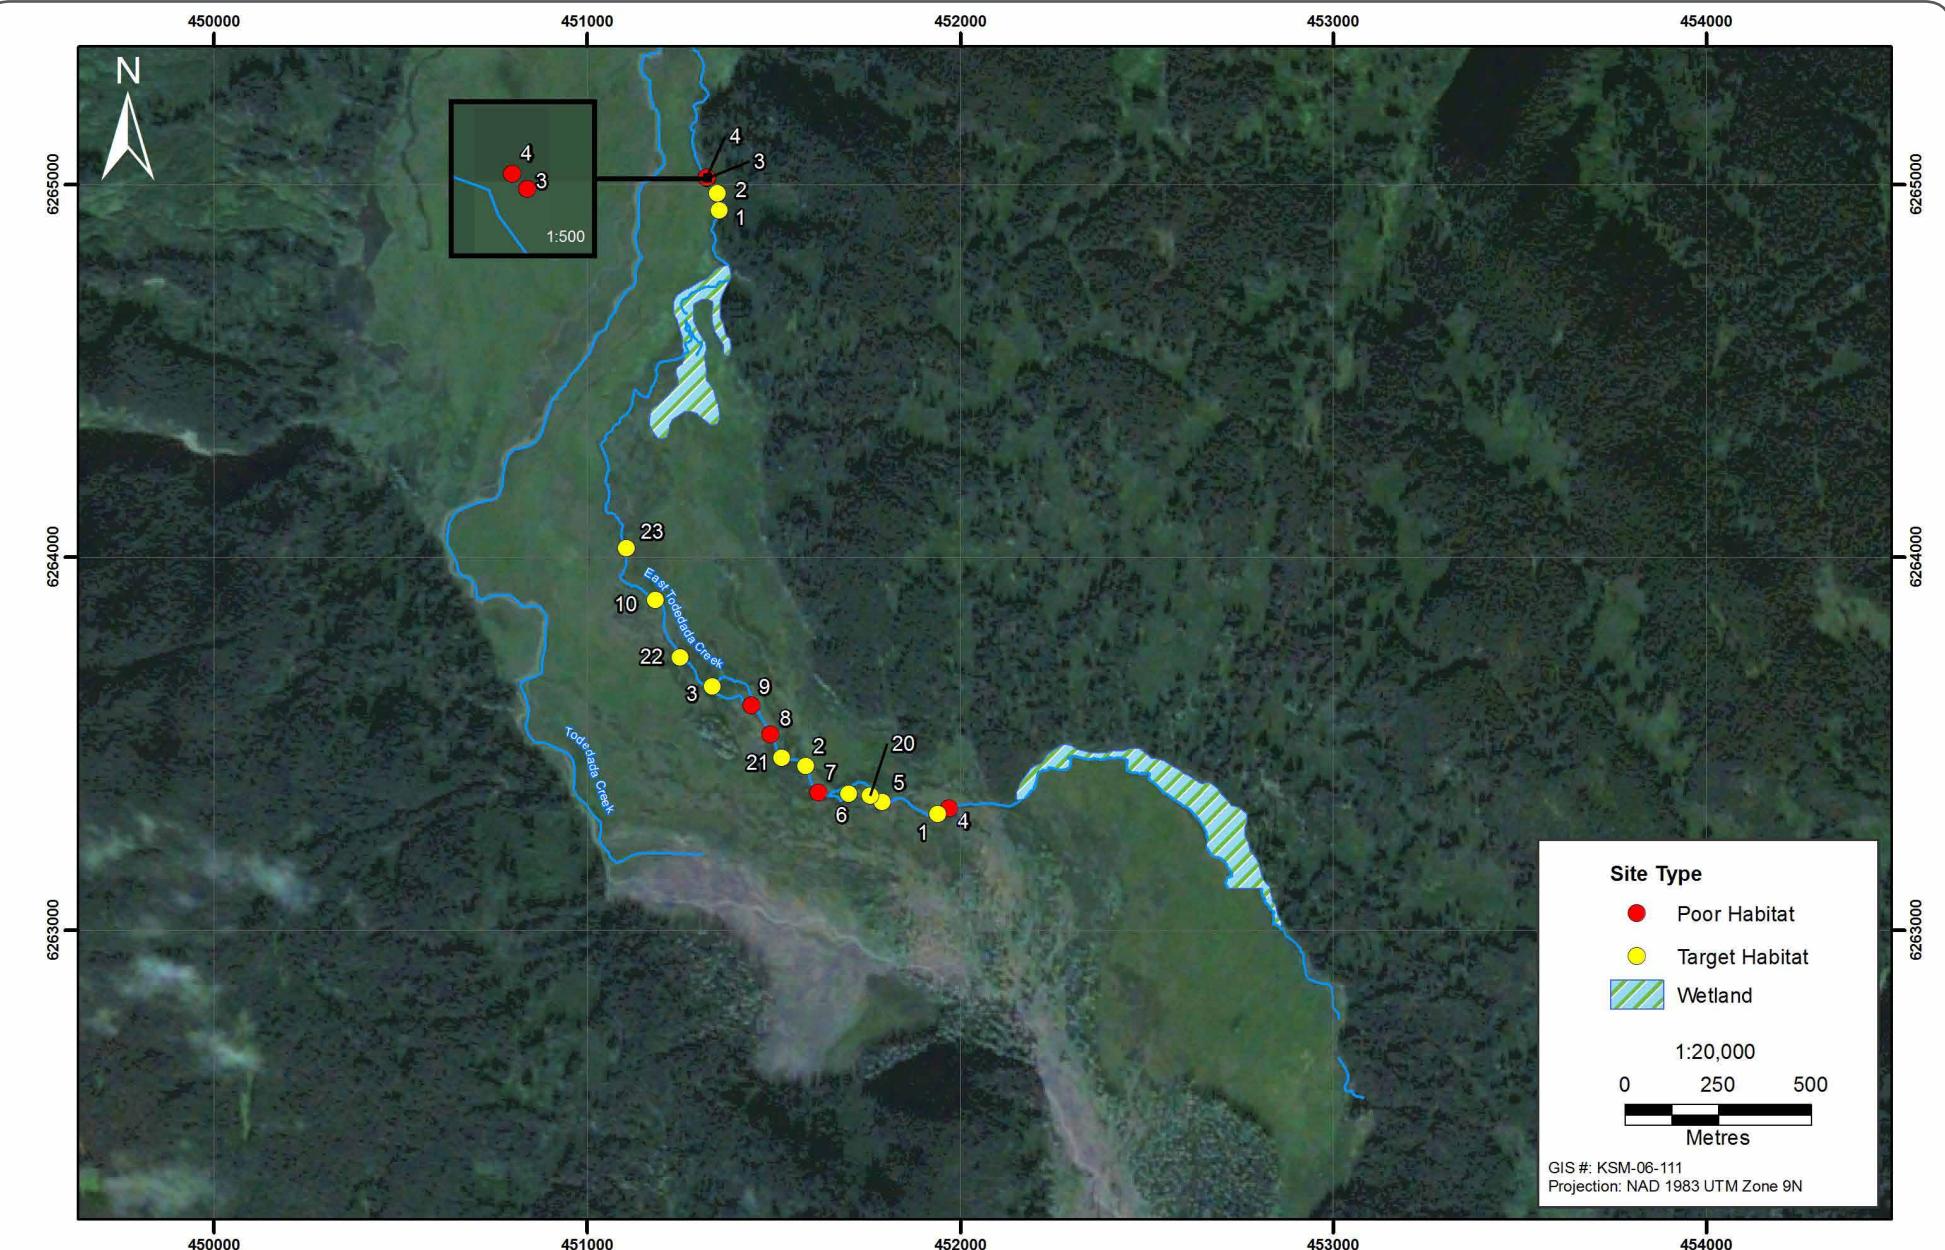

Appendix 7.3-1 presents the sample site location data. Appendix 7.3-2 presents site specific stream habitat data in raw format. The location of stream sample sites are shown in Figures 7.3-1 to 7.3-6. Summary statistics for stream site length, bankfull area and wetted area are shown in Table 7.3-1. Summary statistics for stream site channel characteristics are shown in Table 7.3-2. Target and poor habitat site wetted widths were similar within each treatment stream. Wetted widths of reference streams were not similar to treatment streams, because reference streams are not selected to be identical to the treatment streams (Roni 2005). Target and poor habitat site wetted areas were not similar within each treatment stream. This is expected due to differences site length, habitat unit type (e.g., riffle-pool versus run) hydraulics and stream morphology (Bison et al. 2006).

The results of cumulative mean instream cover (weighted by wetted area) demonstrate that instream cover at poor habitat (run/cascade) sites is consistently 50% lower compared to target habitat (riffle-pool) sites within the same stream (Figure 7.3-7). Overhanging vegetation provides the majority of cover within poor habitat; while pools provide the majority of cover within target habitat. The results of cumulative mean instream cover demonstrate that target habitat provides a greater diversity of cover types. LWD is consistently present in target habitats, but generally absent (or low % instream cover) in poor habitats. East Todedada Creek target habitat is an exception because riparian vegetation is entirely composed of shrubs.

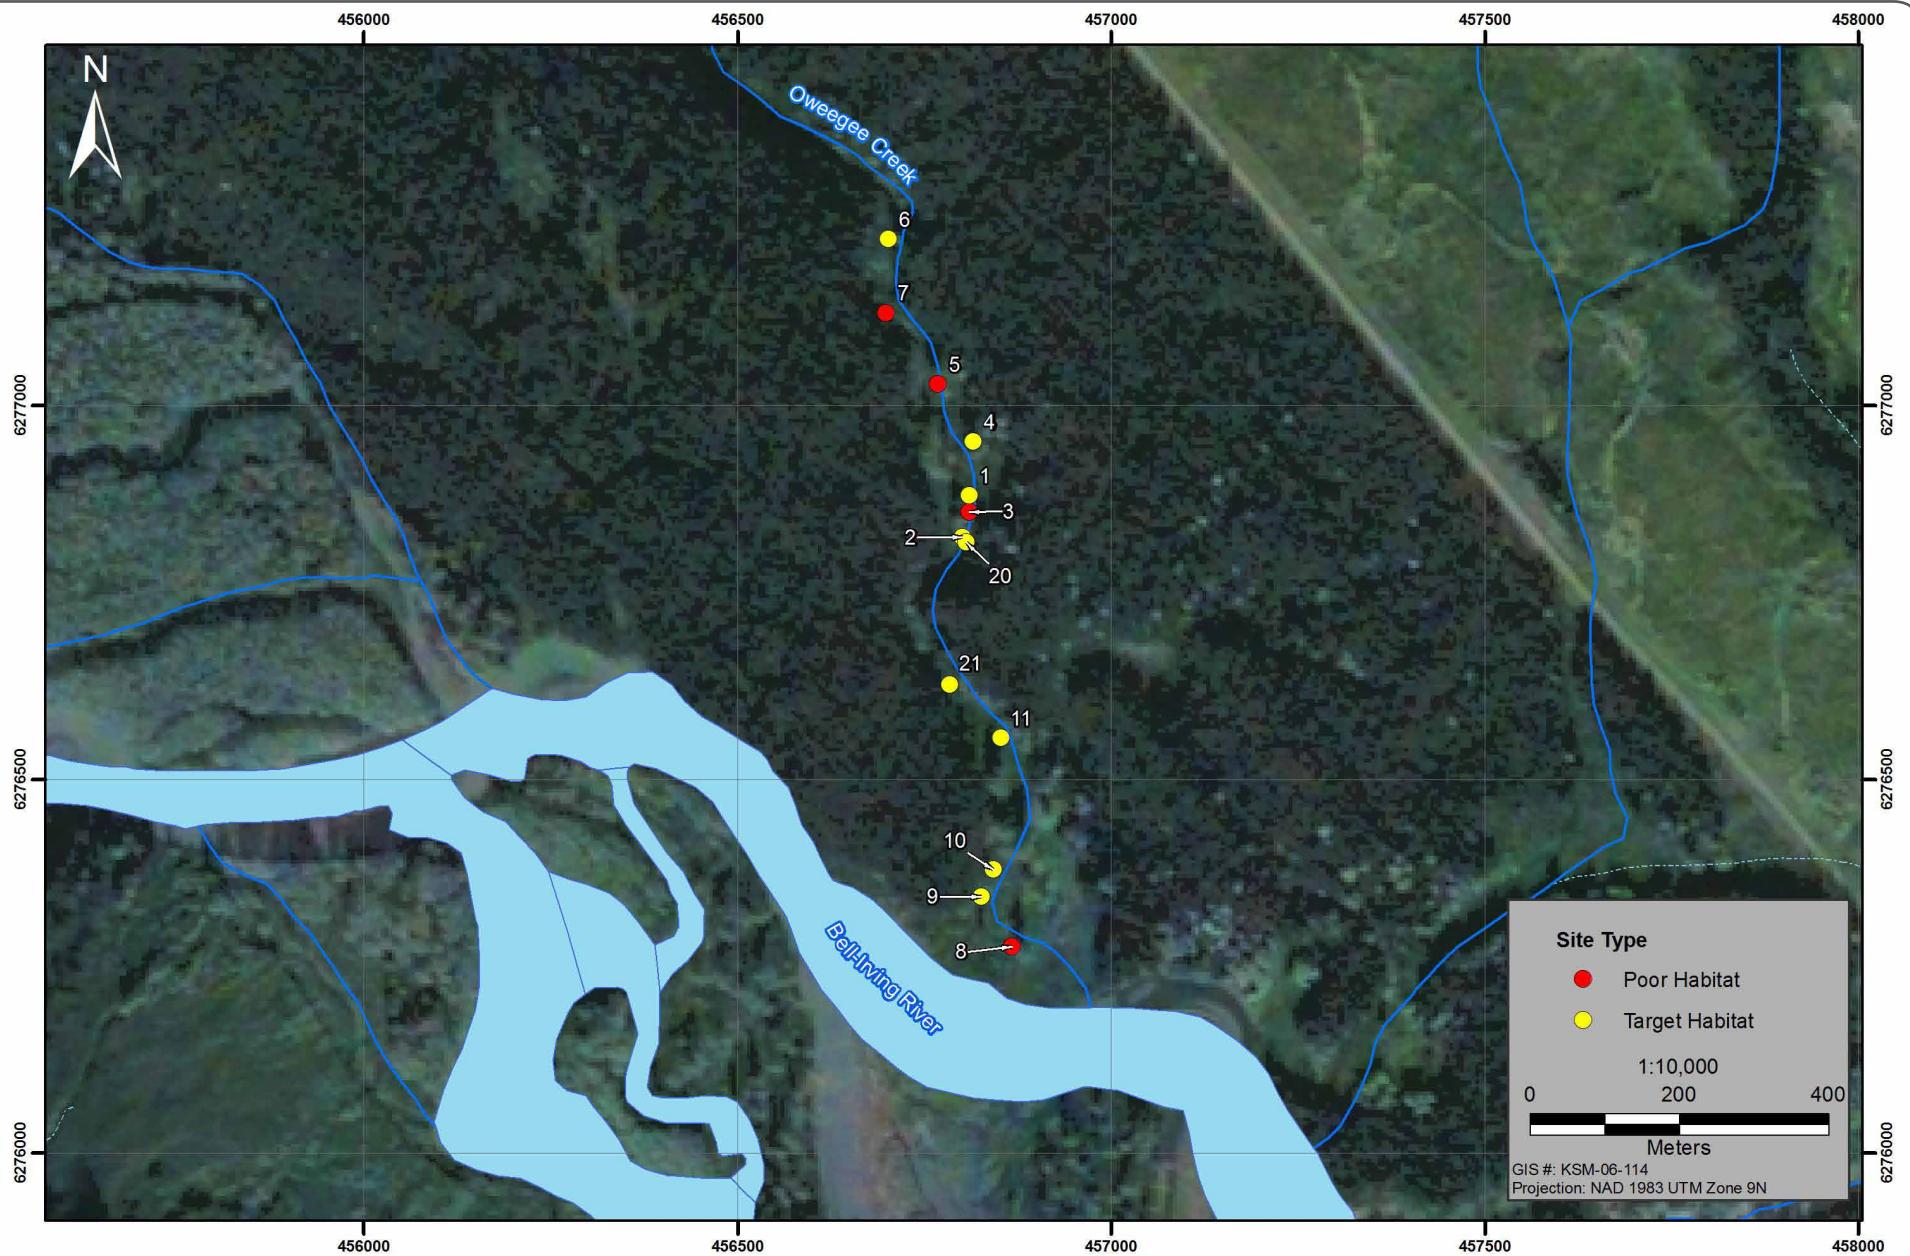

The results of cumulative mean instream cover (weighted by wetted area) for target pool habitat demonstrate that pools provide a diversity of habitat cover types for fish (Figure 7.3-8). This statement is consistent with the previous statements about target habitat. Residual pool depth varied between stream reaches (Table 7.3-3), which is related to differences in stream energy, morphology and instream habitat (Bison et al. 2006). In addition, target pool habitat was not sampled in Snowbank Creek due to the lack of pool habitat throughout the reach.

Substrate is a key component of fish habitat due to its physical properties and its biological functions (e.g., invertebrate habitat, cover for fish and incubator of fish embryos). The results of mean bed substrate composition (weighted by wetted area) demonstrate that poor habitat sites consist of larger substrates compared to target habitat sites within the same stream (Figure 7.3-9). Mean bed substrate composition provides an indication of available fish cover; such as a greater percentage of boulders in poor habitat sites. Larger substrates are resistant to scour and movement at all but peak flows in higher velocity habitat types. The results of mean bed substrate composition demonstrate that target habitat sites generally consist of a greater diversity and uneven composition of substrates types compared to poor habitat sites within the same stream.

Comparisons of mean LWD tally per site demonstrate that LWD is greater in target habitat than poor habitat within the same stream (Figure 7.3-10). LWD causes horizontal stream energy and laminar flow to be interrupted and deflected into the banks and bed causing pools to be scoured while also providing cover for fish.

All of the above data provides information to support the development fish habitat compensation designs. The fish habitat data provides information on existing natural templates for future fish habitat prescriptions.

7.3.2 CPUE

Fish species sampled in the conceptual fish habitat compensation sites are presented in Table 7.3-4. Coho salmon and Dolly Varden are the most dominant species present within the stream compensation sites. Lower Oweegee Creek has the most diverse fish community with a total of five species.

Table 7.3-4. Streams: Fish Species Sampled through Electrofishing and Minnow Trapping, 2011

Type	Watershed	Fish Species Caught						
		Coho Salmon	Chinook Salmon	Dolly Varden	Bull Trout	Rainbow Trout	Mountain Whitefish	Longnose Sucker

Treatment	East Todedada Creek - Upper	X		X				
Treatment	Oweegee Creek - Lower	X	X			X	X	X
Treatment	Snowbank Creek	X	X	X		X		

'X' indicates fish species caught

To calculate life history stage specific CPUE (fry, parr, adult), each captured fish was assigned a life history stage generated from length frequency histograms and fin ray age data. In general, plotted histograms for lengths recorded electrofishing and minnow trapping showed clear length-frequency "cut-offs" between age-0 fry and age-1 parr, which were in agreement with the cut-offs suggested by scale age data for Dolly Varden, coho salmon, Chinook salmon and rainbow trout (Figures 7.3-11 and 7.3-12). However, in cases where sample size was insufficient ($n < 100$), length frequency histograms did not suggest clear length cut-offs between life history stages.

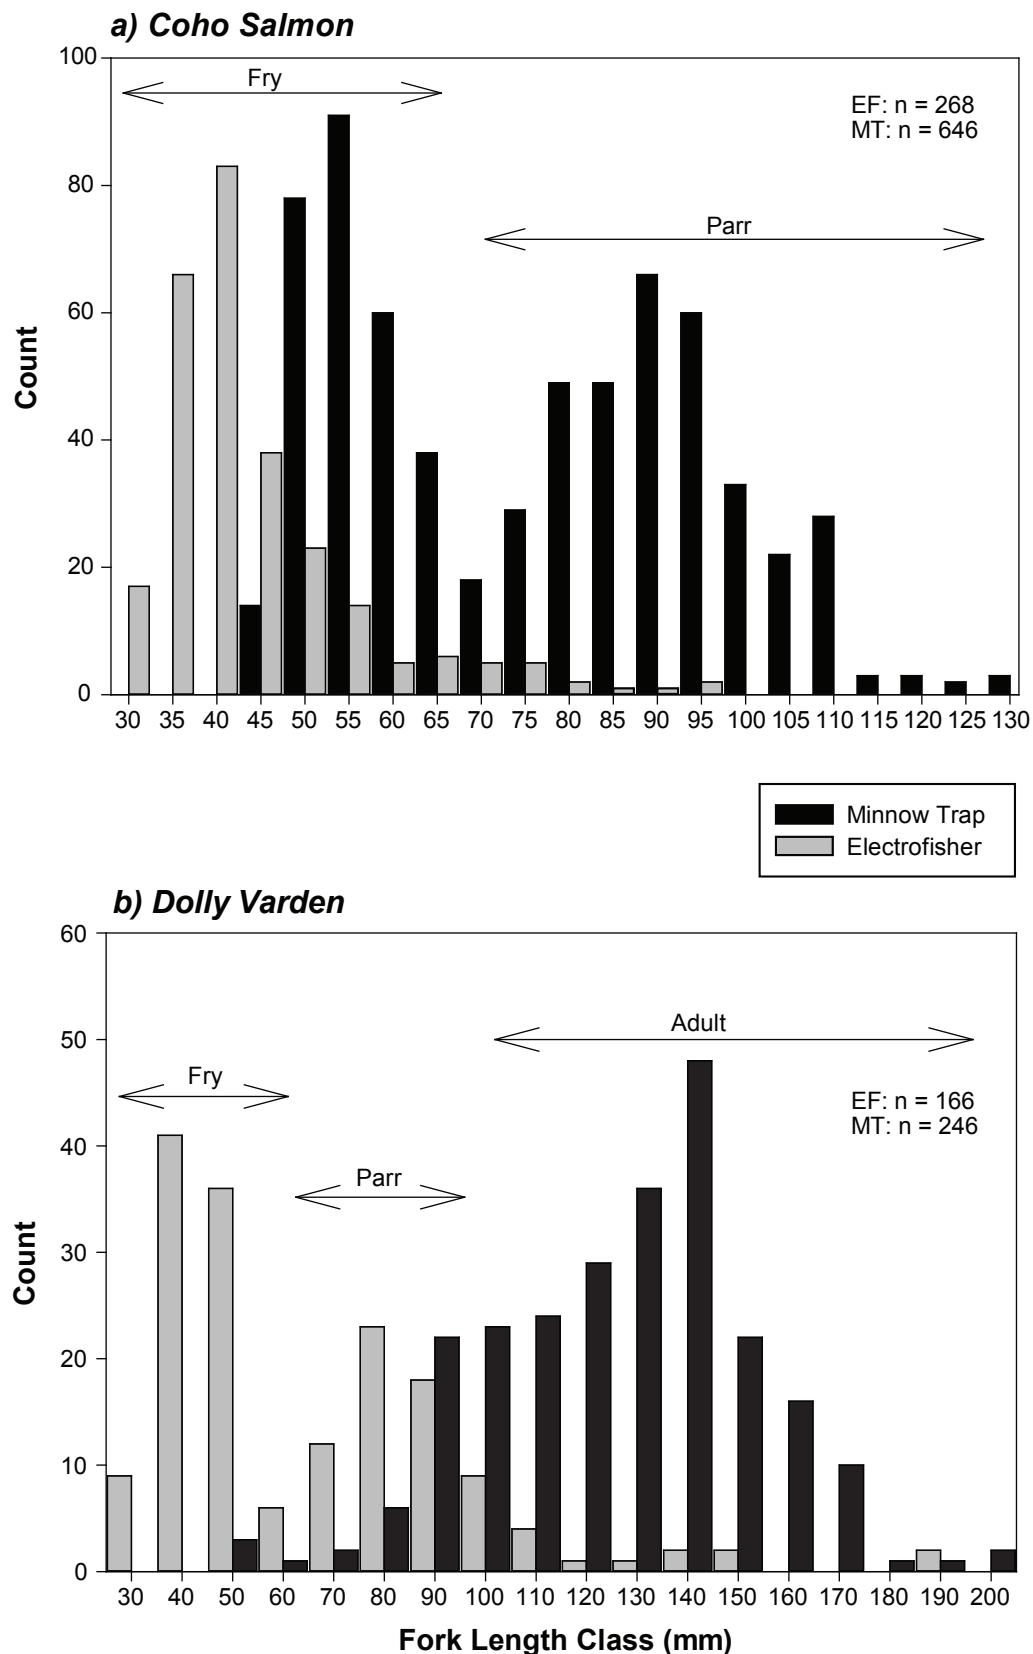

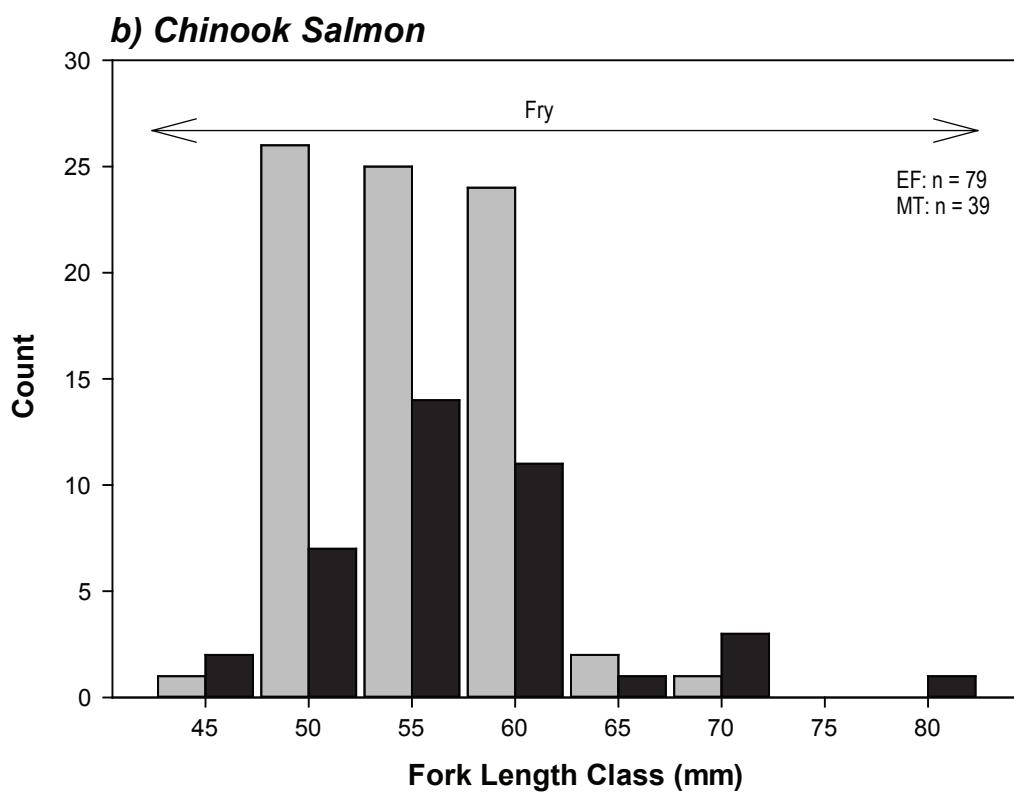

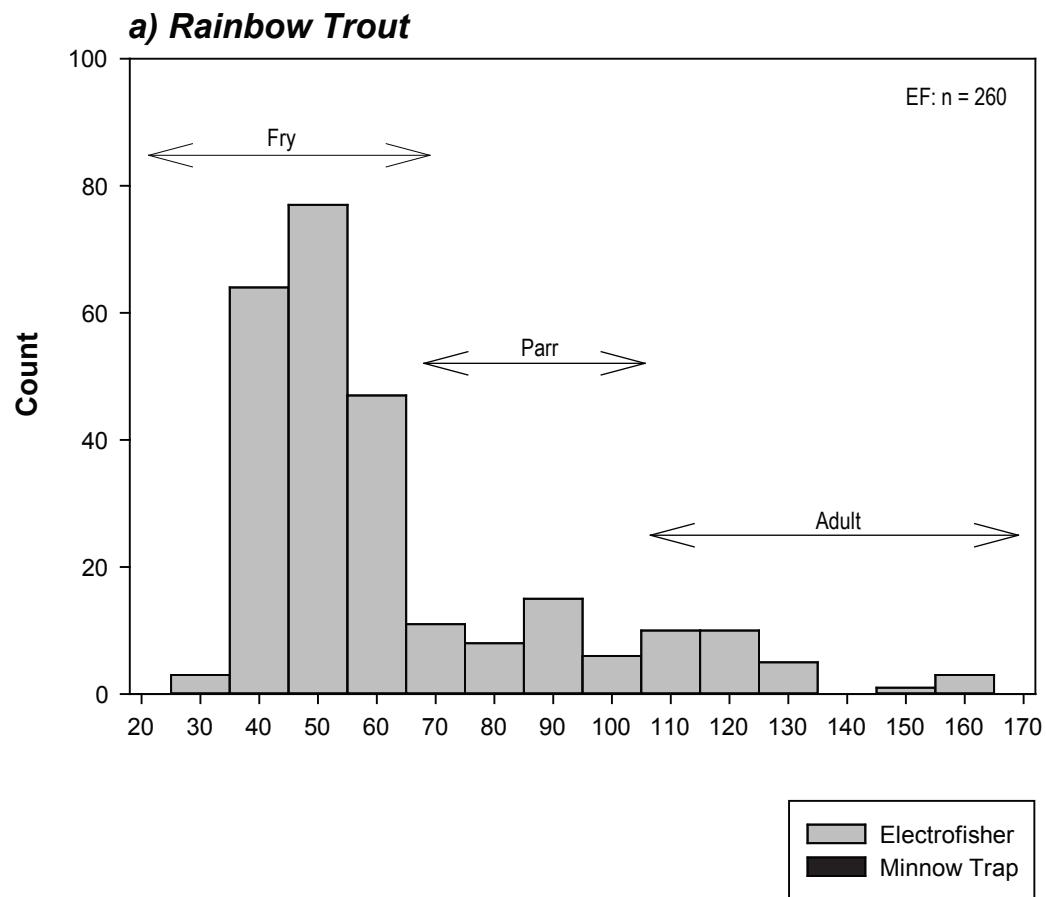

Figure 7.3-11

CPUE was calculated for each gear type (i.e., backpack electrofisher and minnow trap). A dual gear approach was utilized within target habitat sites due to gear efficiency and size selectivity in pool habitat units (Murphy and Willis 1996; Johnson et al. 2007). Electrofishing is effective at sampling shallow water depths with low habitat complexity (Jones and Stockwell 1995); such as riffle, run and cascade habitat types. However, electrofishing is less effective at sampling deep, non-wadable pools, pools with abundant habitat complexity or pools with high turbidity (Jones and Stockwell 1995). Teigen Creek and East Todedada Creek are examples where electrofishing is less effective at sampling pool habitats, thus minnow traps were used. However, CPUE between gear types are not comparable because of differences in size selectivity. Figure 7.3-13 demonstrate that minnow trapping is selective of longer fish, specifically Dolly Varden and coho salmon, compared to electrofishing. The fork length histogram for rainbow trout shows that minnow trapping was ineffective at capturing fish in pool habitats (Figure 7.3-14). This can likely be attributed to the abundance of high rainfall events during the sampling period (Rescan 2012), which resulted in higher velocities in Oweegee Creek pool habitats. Therefore, locating low velocity sites to set minnow traps was problematic. The fork length histogram for Chinook salmon shows no size selectivity of the gear because only one age class (i.e., fry) was present in the streams sampled (Rescan 2009, 2010, 2011).

Tables 7.3-5 and 7.3-6 shows mean electrofishing and minnow trapping effort by stream. The predetermined 24 h minnow trap set time was consistent (i.e., never was below the minimum set time and hauls were within a 2 h range) within and between stream sites. Electrofishing effort varied within stream sites because site length varied depending upon the length of the habitat units.

Table 7.3-5. Streams: Mean Stream Electrofishing Sampling Effort, 2011

Appendices 7.3-3 and 7.3-4 present species effort and catch data for electrofishing and minnow trapping, respectively. Appendices 7.3-5 and 7.3-6 each present a summary of descriptive statistics for standard and bootstrap electrofishing and minnow trapping CPUE means, respectively. Comparisons of standard and bootstrap CPUE means indicate that the means are similar (< 0.01% difference) when sample size is greater than five; however, when sample size is less than five, the mean difference is greater (> 2% difference). Furthermore, the SD of bootstrapped means were similar to the SE of the standard mean when sample size was greater than five. Because replication was low, the bootstrapped confidence intervals are likely narrower than true confidence intervals, whereas the regular confidence intervals are likely larger than the true confidence intervals. For these reasons, bootstrap means are presented in illustrative comparisons.

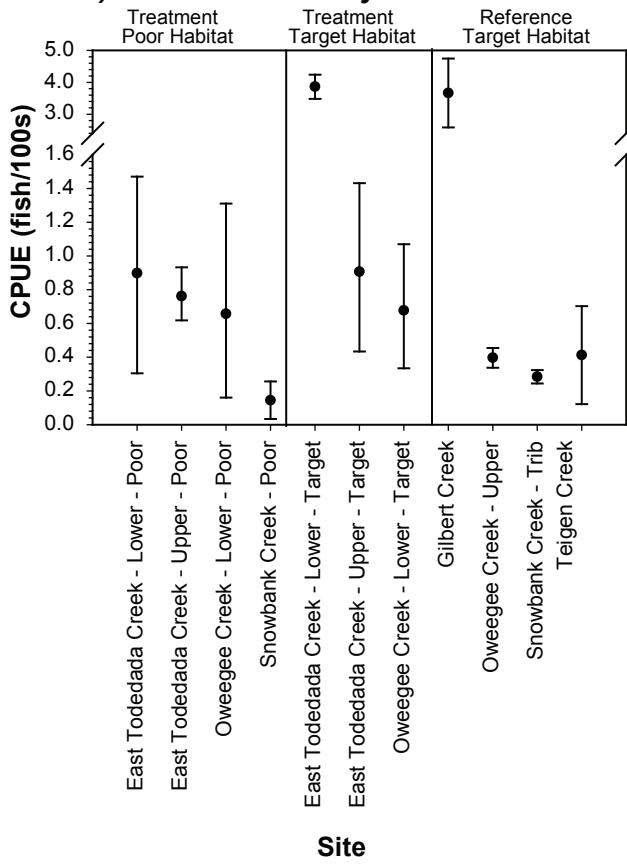

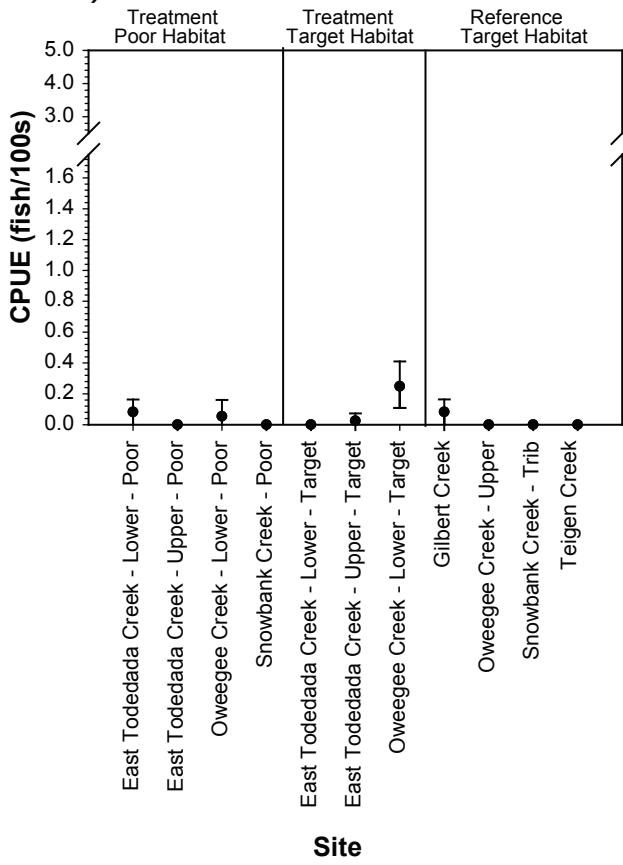

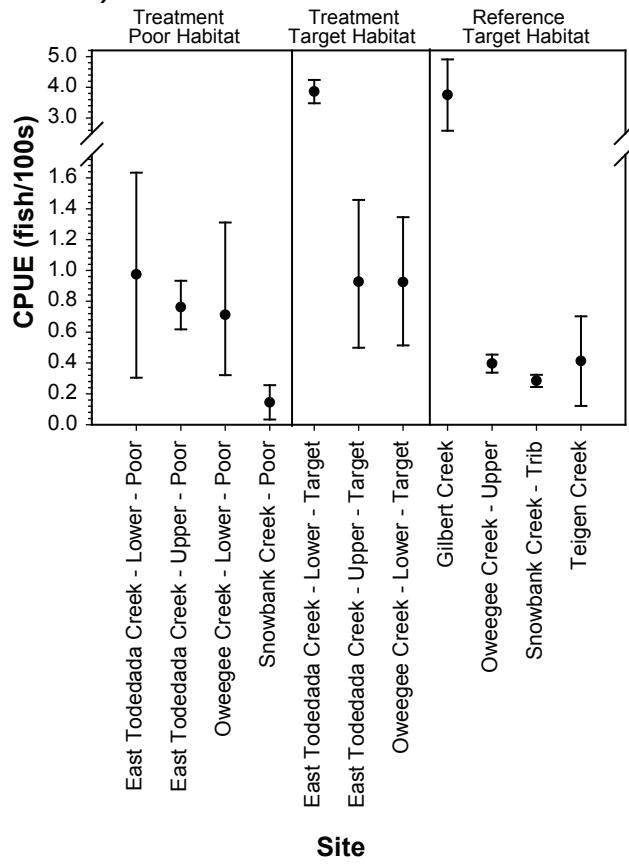

Stream CPUE was analysed using a two factor ANOVA testing for differences in CPUE between habitats types (poor and target) and stream. Stream was used as a block in the ANOVA because samples from within a stream are not independent (Guy and Brown 2007). Only streams that had greater than three CPUE measurements taken from both poor and target habitats were included in the analyses. As a result, only East Todedada Creek Lower, East Todedada Creek Upper and Oweegee Creek Lower fit these criteria. In cases where many zeros (no catches) are present, standard parametric statistics were not performed as the results are unreliable in the presence of large violations of the assumptions of ANOVA (Guy and Brown 2007). Therefore, statistical analysis of CPUE was only completed for the following species: coho salmon, Dolly Varden (only in East Todedada Creek Upper and Lower) and rainbow trout (only in Oweegee Creek Lower).

Electrofishing CPUE of coho salmon (all life stages) was not statistically significant between habitat type or stream (ANOVA - Habitat, $F_{1,20} = 0.31, P = 0.58$; ANOVA - Site, $F_{2,20} = 0.34, P = 0.72$). In East Todedada Creek Lower and Oweegee Creek Lower, graphical comparison of CIs indicates that mean coho salmon fry CPUE is higher in target habitat versus poor habitat (Figure 7.3-15). Minnow trapping CPUE of coho salmon (all life stages) was statistically significant (ANOVA, $F_{5,25} = 6.74, P < 0.01$) between target habitat stream sites (Figure 7.3-16), which can largely be attributed to fry CPUE.

Electrofishing CPUE of Dolly Varden (all life stages) was not statistically significant between habitat type or stream (ANOVA - Habitat $F_{1,11} = 1.74, P = 0.21$; ANOVA - Site $F_{1,11} = 0.18, P = 0.68$). In East Todedada Creek Lower, graphical comparison of CIs indicates that mean Dolly Varden adult, fry, parr and all life stage CPUE is higher in target habitat versus poor habitat (Figure 7.3-17). In East Todedada Creek Upper, graphical comparison of CIs indicates that mean Dolly Varden parr CPUE is higher in target habitat versus poor habitat (Figure 7.3-17). Minnow trapping CPUE of Dolly Varden (all life stages) was statistically significant (ANOVA, $F_{3,16} = 10.69, P < 0.01$) between target habitat sites (Figure 7.3-18). The data demonstrates that Dolly Varden parr and adults utilize pool habitat, whereas fry were not sampled in pool habitats but are dominant in riffle habitats effectively sampled by the electrofisher.

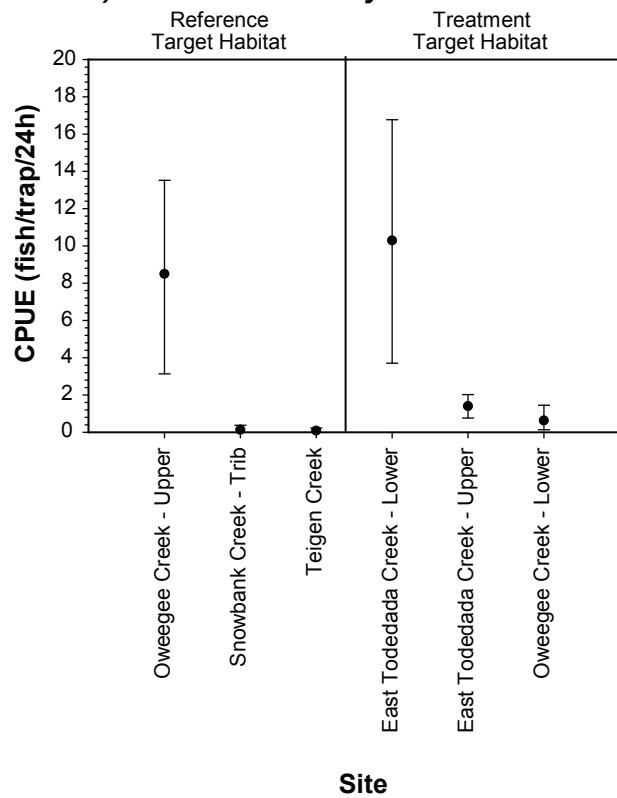

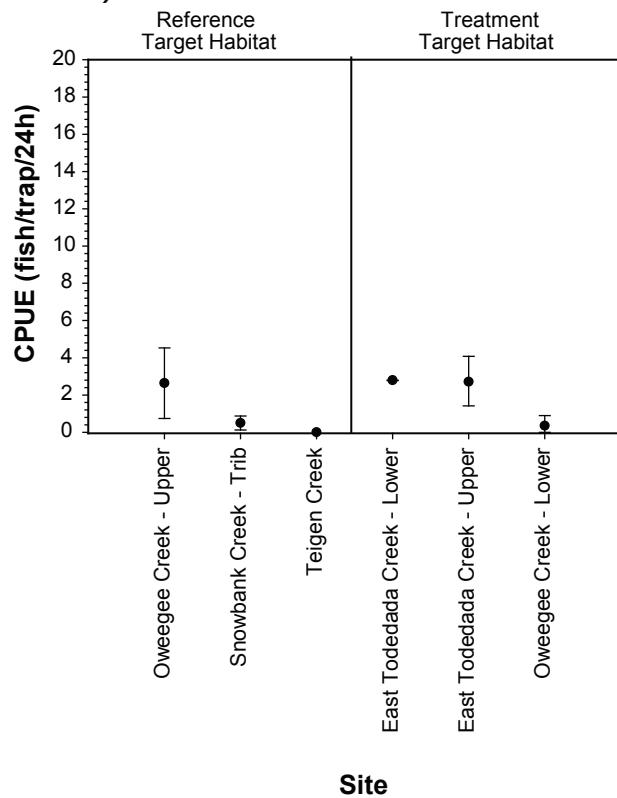

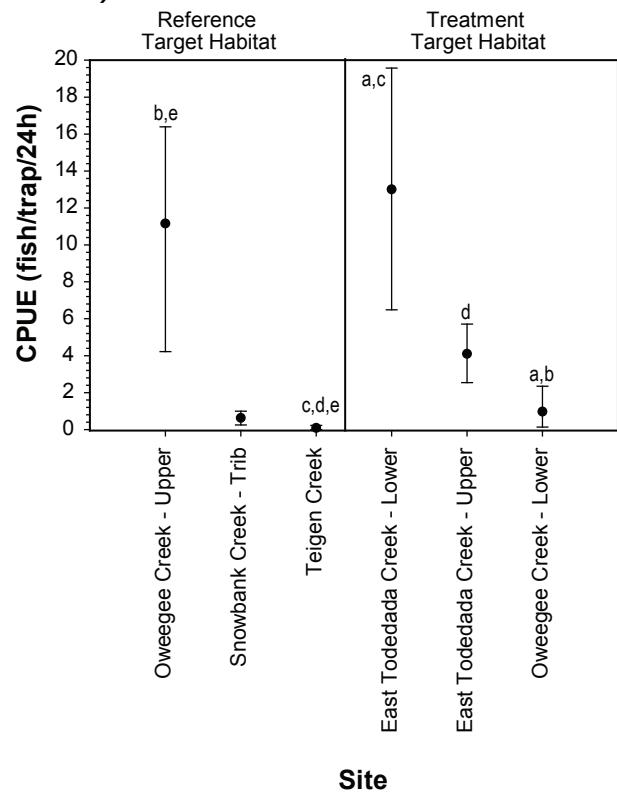

Electrofishing CPUE of rainbow trout (all life stages) was not statistically significant between habitat types in Oweegee Creek (ANOVA, $F_{1,8} = 0.01, P = 0.99$). In Oweegee Creek Lower, graphical comparison of CIs indicates that mean rainbow trout parr CPUE is higher in target habitat versus poor habitat (Figure 7.3-19). Graphical comparison of CIs indicates that mean rainbow trout adult, fry, parr and all life stage CPUE is higher in Teigen Creek target habitat versus Snowbank Creek poor habitat (Figure 7.3-19). Minnow trapping CPUE of rainbow trout (all life stages) was not statistically compared due to the abundance of zero catch instances (Figure 7.3-20).

Graphical comparison of CIs indicates that electrofishing CPUE of Chinook salmon (fry) is higher in Teigen Creek target habitat versus Snowbank Creek poor habitat (Figure 7.3-21). Minnow trapping CPUE of Chinook salmon is shown in Figure 7.3-22 for Teigen Creek. This data clearly demonstrates that Chinook fry utilize and are more abundant in target habitat, which is absent in Snowbank Creek.

Total abundance cannot be calculated or compared between stream sites, except East Todedada Creek target habitat sites, due to the inability to enclose sites. The Schnabel Method for estimating population size of target habitat from multiple mark-recapture samples was used for East Todedada Creek. The estimated population size of Dolly Varden utilizing target habitat is 31 (95% CI: 15 - 47). The estimated population size of coho salmon utilizing target habitat is 19 (95% CI: 9 - 29).

The above CPUE data indicates that, although variable, differences in species-specific CPUE between target and poor habitat are apparent. With respect to each gear type, target habitat CPUE is generally higher than poor habitat CPUE, and in certain cases is statistically significant. Biomass, density or total abundance cannot be calculated or compared between stream sites, except East Todedada Creek, due to the inability to enclose sites (e.g., three-pass depletion or mark-recapture methods) and differences in gear type between habitat types (i.e., electrofish and minnow trap). However, it is apparent that biomass/density/abundance is higher in target habitats than poor habitat because minnow traps must be used in combination with electrofishing to effectively sample target pool habitats (i.e., parr and sub-adults are more abundant in pool habitat types).

7.3.3 Biological

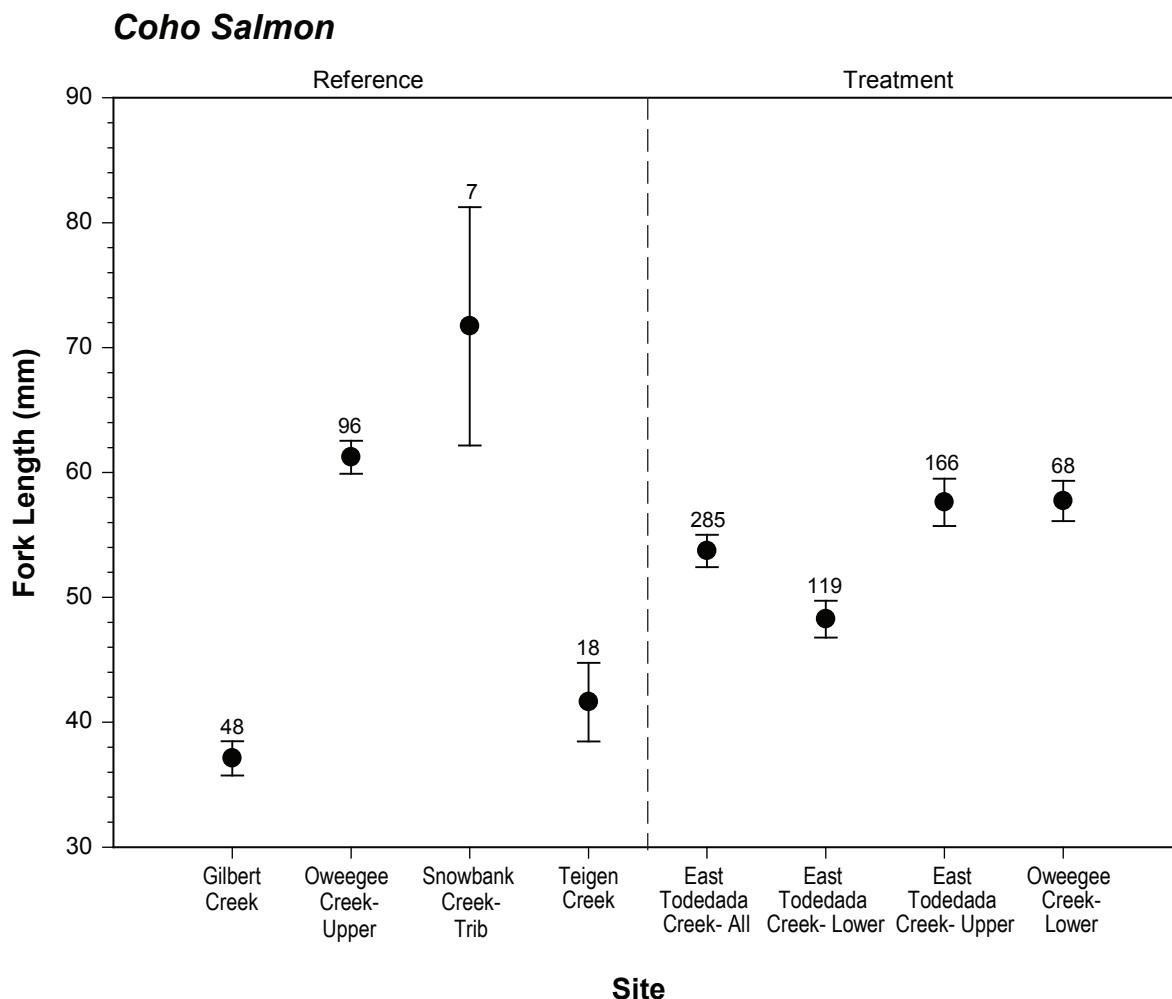

7.3.3.1 Condition

Appendix 7.3-7 presents species-specific biological data for stream habitats. Appendix 7.3-8 presents a summary of descriptive statistics for standard and bootstrap fork length, weight and condition means. Comparisons of regular and bootstrap CPUE means indicate that the means are similar (< 0.01% difference) when sample size is greater than five; however, when sample size is less than five, the mean difference is greater (> 2% difference). Furthermore, the SD of bootstrapped means were similar to the SE of the standard mean when sample size was greater than five. Because replication was high, standard means are presented in illustrative comparisons.

The data collected represents the condition of late summer stream rearing fish. Means were analysed using a one factor ANOVA testing for differences in mean between streams. Where transformation of data failed to meet assumptions of parametric ANOVA, a non-parametric Kruskal-Wallis or Mann-Whitney U test was used.

Mean fork length (Kruskal-Wallis, $H = 134.54$, $df = 7$, $P < 0.01$) and weight (Kruskal-Wallis, $H = 137.41$, $df = 7$, $P < 0.01$) of coho salmon were statistically significant between streams. Table 7.3-7 presents the results of the multiple comparisons test for coho salmon. There are multiple differences between streams; however, the data demonstrates that the abundance of parr sampled/present in each creek and gear type used has an influence on the mean length and weight statistical differences between streams (Figures 7.3-23 to 7.3-25). There are significant differences in condition (Kruskal-Wallis, $H = 84.88$, $df = 7$, $P < 0.01$) between streams (Figure 7.3-26), which is similar to differences reported for mean fork length and weight. Differences in condition could be attributed to local habitat conditions and prey availability in streams (Murphy and Willis 1996).

Mean fork length (Kruskal-Wallis, $H = 12.86$, $df = 5$, $P = 0.02$) and weight (Kruskal-Wallis, $H = 11.18$, $df = 5$, $P = 0.04$) of Dolly Varden were statistically significant between streams. The results of the multiple comparisons test indicate that there was a significant difference in mean fork length and weight between East Todedada Creek Lower and East Todedada Creek Upper (Figures 7.3-27 and 7.3-28). The data demonstrates that the abundance of parr and adults sampled/present in each creek and gear type has an influence on the mean length and weight between streams (Figure 7.3-29). There are significant differences in condition (Kruskal-Wallis, $H = 13.01$, $df = 5$, $P = 0.02$) between streams (Figure 7.3-30). Despite the significant differences in the non-parametric Kruskal-Wallis test, there are no significant differences in the multiple comparisons test. This is because the multiple test result in less power to detect differences, which suggests the differences between streams are small, yet significant when analyzed together.

Mean fork length (Kruskal-Wallis, $H = 66.38$, $df = 4$, $P < 0.01$) and weight (Kruskal-Wallis, $H = 63.39$, $df = 4$, $P < 0.01$) of rainbow trout were statistically significant between streams. Table 7.3-7 presents the results of the multiple comparisons test for rainbow trout. There are multiple differences between streams; however, the data demonstrates that the abundance of fry sampled/present in Oweegee Creek (upper and lower) has an influence on the mean length and weight statistical differences and is dependent upon the effectiveness fish capture technique and their size-selectivity (Figures 7.3-31 to 7.3-33). There are significant differences in condition (Kruskal-Wallis, $H = 27.54$, $df = 4$, $P < 0.01$) between streams (Figure 7.3-34). The significant differences are between Oweegee Creek Lower and Teigen Creek (Table 7.3-7).

Statistical analysis was not conducted for Chinook salmon because of insufficient sample size. Sample size was only sufficient for Teigen Creek ($n = 118$) and cannot be compared statistically with Snowbank Creek (Figures 7.3-35 to 7.3-37).

7.3.3.2 Growth

Appendix 7.3-7 presents species-specific biological data for stream habitats. Appendix 7.3-9 presents a summary of descriptive statistics for standard and bootstrap mean ages. The SD of bootstrapped means were similar to the SE of the standard mean when sample size was greater than five. Since replication was high, standard means are presented in illustrative comparisons.

The data collected represents the growth of late summer stream rearing Dolly Varden. Sample size was only sufficient to construct a growth model for East Todedada Creek Upper ($n = 30$), which had a mean age of 3.2 years (+/- 0.2 SE).

Von Bertalanffy growth curves and a size-at-age linear regression was conducted for Dolly Varden in East Todedada Creek (Figure 7.3-38). The Akaike weights show the magnitude of support for each model; the model with the highest weight being the best fit model of three models compared. The fit of the all models was poor. However, the two-parameter (zero) von Bertalanffy growth model fit through zero performed best compared to other models (e.g., twice as good as the three-parameter (full) von Bertalanffy model). The two-parameter (zero) von Bertalanffy growth model predicted an asymptotic fork length of 159 mm with a growth coefficient (K) of 0.52 year^{-1} .

7.4 WETLANDS

7.4.1 Fish Habitat

Appendix 7.4-1 presents the sample site location data. The location of wetland sample sites is shown in Figures 7.4-1 and 7.4-2.

Summaries of wetted widths, area and depths are shown in Table 7.4-1. The area of treatment wetlands ranged from 0.08 to 0.85 ha. In comparison, reference wetlands ranged from 0.05 to 1.44 ha. Maximum depth ranged from 0.8 to 2 m in both wetlands types. All reference wetlands were of similar size and depth to those planned for off-channel habitat creation projects.

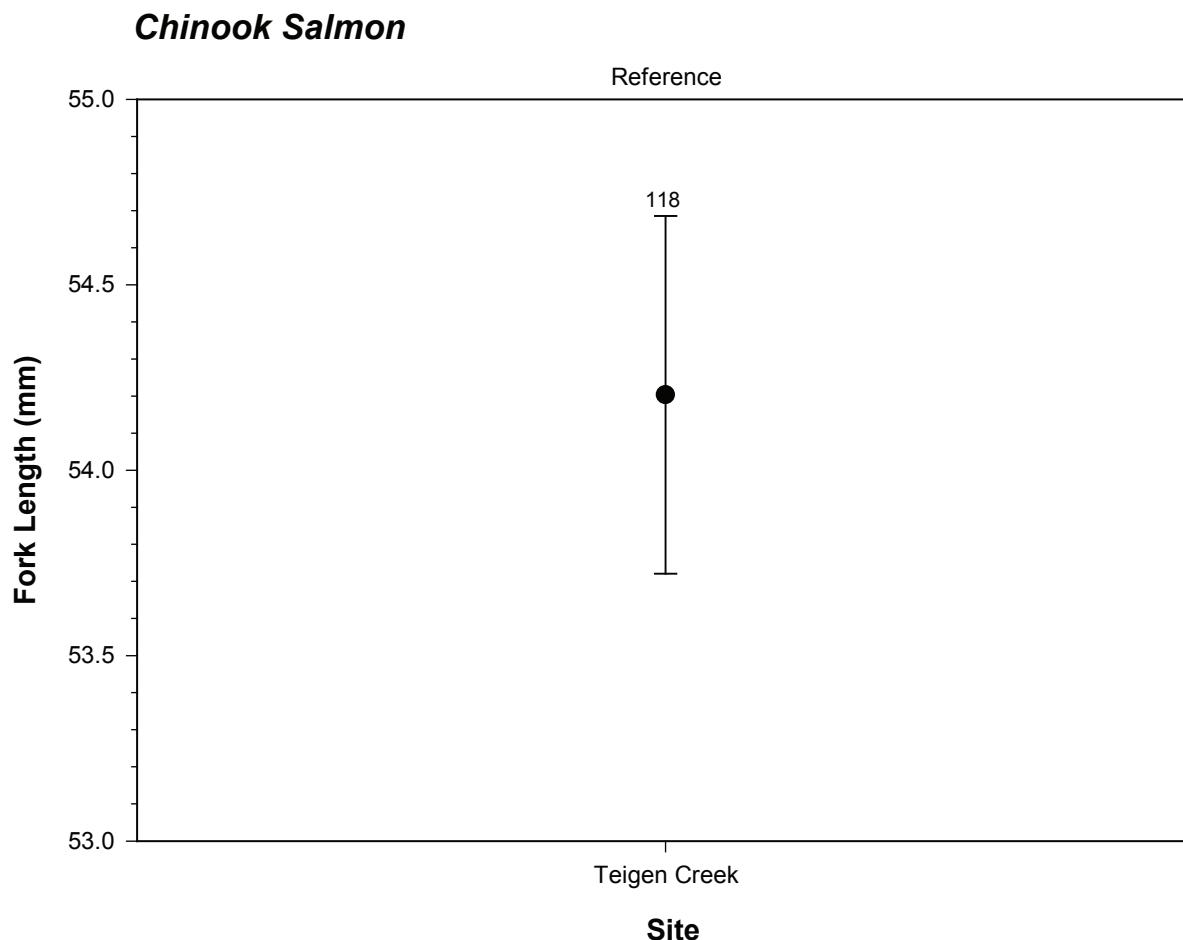

All treatment wetlands were selected based upon previous fieldwork that confirmed them as fish bearing. However, prior fish presence information was not necessarily known for reference wetlands. Of the ten reference wetlands selected, five were confirmed as fish bearing. These wetlands were: Oweegee Creek Wetland 1, Teigen Creek Wetland 4, Treaty Creek Wetland 1, 3 and 7 (Plates 7.4-1 to 7.4-5).

7.4.2 CPUE

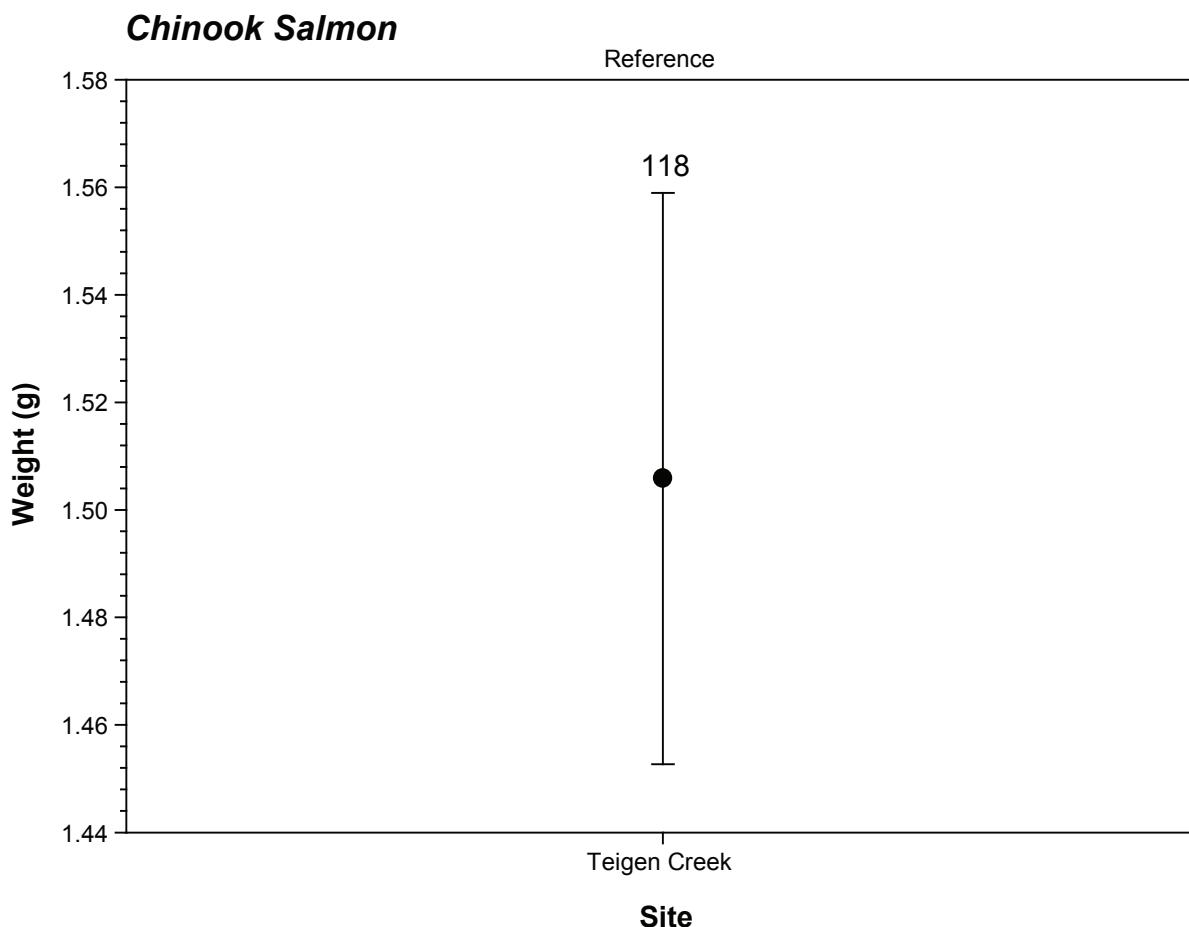

Fish species sampled in the conceptual fish habitat compensation sites are presented in Table 7.4-2. Coho salmon and Dolly Varden are the most dominant species present within the stream compensation wetland sites.

Tables 7.4-3 shows total minnow trapping effort (h) for non-fish bearing wetlands. For fish bearing wetlands, the mean set time was 24.1 h (+/- 0.18 SE) with a range of 20.0 h to 27.3 h.

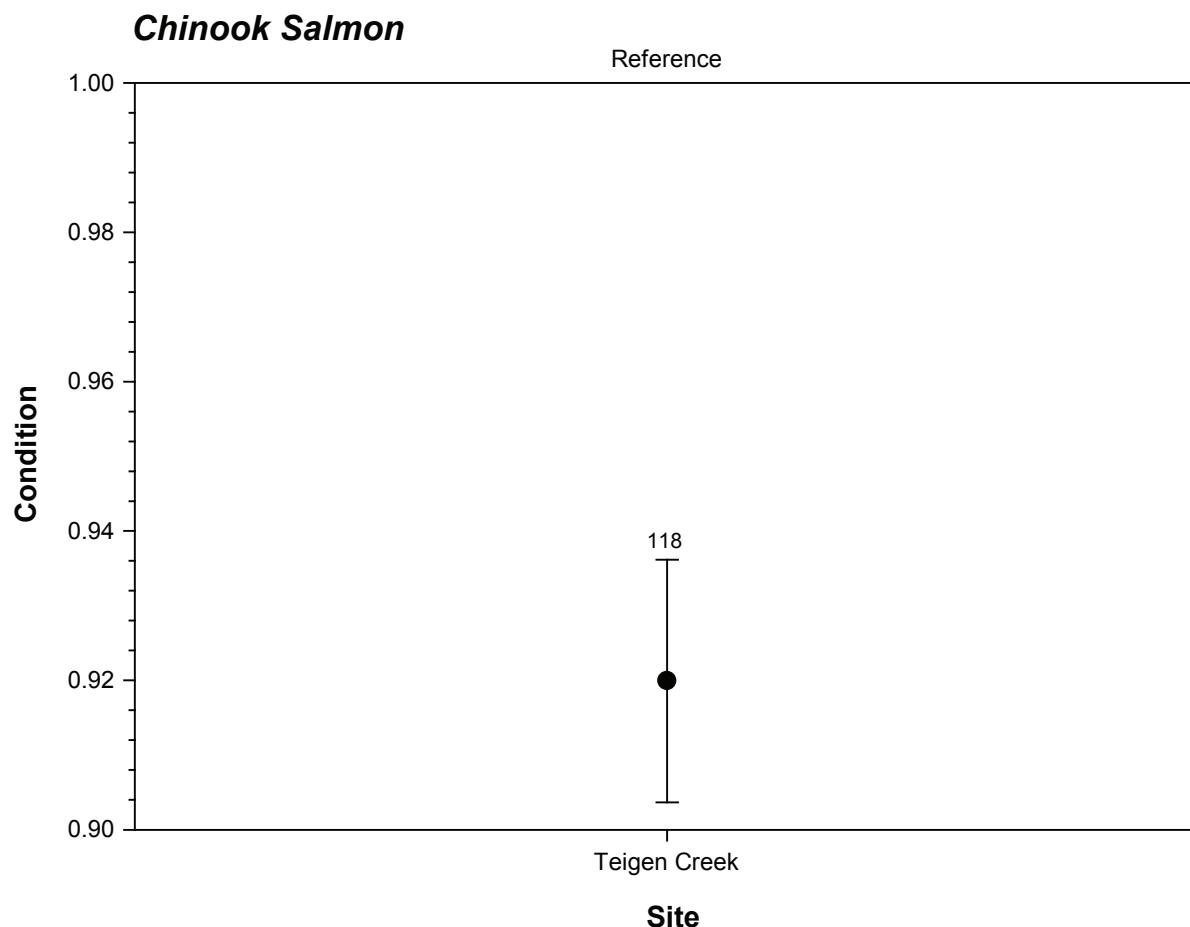

Appendix 7.4-2 presents species-specific effort and catch data for minnow trapping. Appendix 7.4-3 presents a summary of descriptive statistics for standard and bootstrap minnow trapping CPUE means.

Comparisons of standard and bootstrap CPUE means indicate that the means are similar (< 0.01% difference) when sample size is greater than five; however, when sample size is less than five, the mean difference is greater (> 2% difference). Furthermore, the SD of bootstrapped means were similar to the SE of the standard mean when sample size was greater than five. Because replication was low, the bootstrapped confidence intervals are likely narrower than true confidence intervals, whereas the regular confidence intervals are likely larger than the true confidence intervals. For these reasons, bootstrap means are presented in illustrative comparisons.

Wetland CPUE was analysed using a two factor ANOVA testing for differences in CPUE between life history stage (e.g., fry, parr, adult) and wetland. Wetland was used as a block in the ANOVA because samples from within a wetland are not independent (Guy and Brown 2007). Then a one factor ANOVA was used to test for differences in total CPUE, by species, among wetlands. A one factor ANOVA was

not used to test for differences in individual life history CPUE because of lost power in detecting differences when sub-divided.

Minnow trap CPUE of coho salmon was statistically significant between life history stage and wetland (ANOVA - Stage, $F_{3,194} = 10.48, P < 0.01$; ANOVA - Site, $F_{13,194} = 9.75, P < 0.01$). Generally, parr are significantly more abundant in wetlands than fry ($P = 0.04$). The results of the one factor ANOVA indicates that there are significant differences (Table 7.4-4) between coho salmon abundance in wetlands (ANOVA, $F_{13,56} = 24.02, P < 0.01$). Graphical comparison of CIs indicates that mean coho salmon CPUE is higher in Oweegee Creek Wetland 1, Teigen Creek Wetland 4 and East Todedada Creek Compensation Wetland 2 (Figure 7.4-3), which can largely be attributed to parr CPUE. These data also demonstrates that coho salmon are more abundant in reference wetlands compared to treatment wetlands, except East Todedada Creek Wetland 2.

Minnow trap CPUE of Dolly Varden was statistically significant between life history stage and wetland (ANOVA - Stage, $F_{2,194} = 7.94, P < 0.01$; ANOVA - Site, $F_{13,194} = 4.47, P < 0.01$). Generally, adults are significantly more abundant in wetlands than fry ($P < 0.01$) because fry are generally absent from wetland habitats. Adults are significantly more abundant than parr ($P = 0.02$), which is influenced by the abundance of adults in three wetlands (Treaty Creek Wetlands 3 and 7, East Todedada Creek Compensation Wetland 2). The results of the one factor ANOVA indicates that there are significant differences (Table 7.4-4) between Dolly Varden abundance in wetlands (ANOVA, $F_{13,56} = 4.82, P < 0.01$). Graphical comparison of CIs indicates that mean Dolly Varden CPUE is higher in Treaty Creek Wetland 3 (Figure 7.4-4), which can largely be attributed to adult CPUE. These data demonstrate that Oweegee Creek Wetland 1 and Teigen Creek Wetland 4 are not suitable reference wetlands for Dolly Varden. These data also demonstrate that Dolly Varden are more abundant in reference wetlands compared to treatment wetlands, with the exception of East Todedada Creek Wetland 2.

7.4.3 Biological

7.4.3.1 Condition

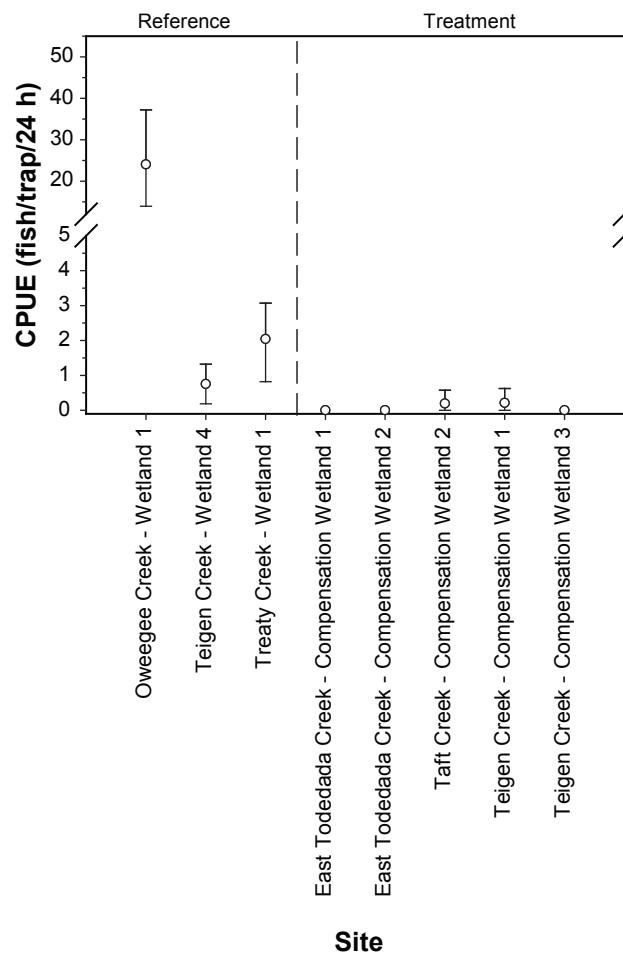

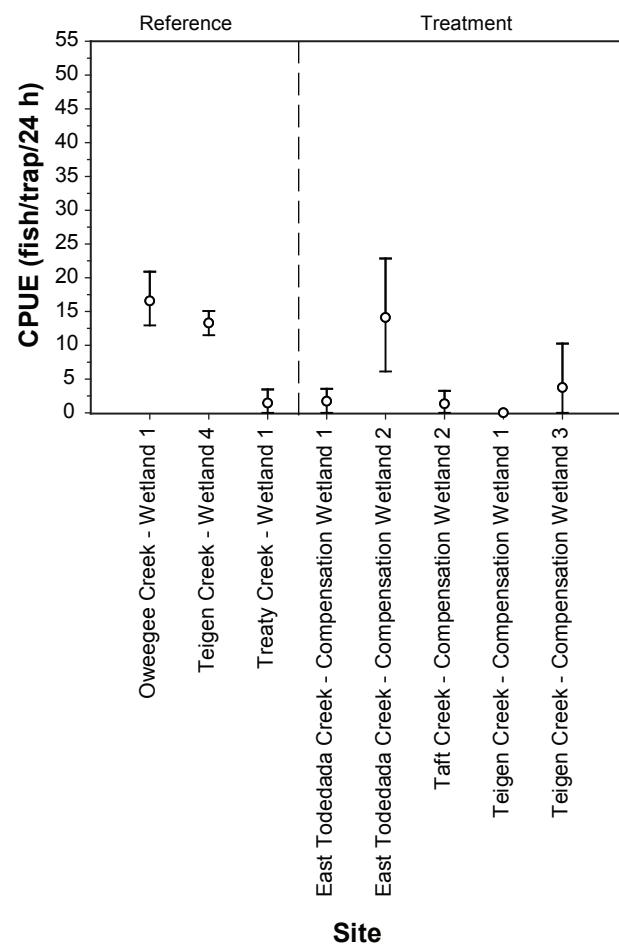

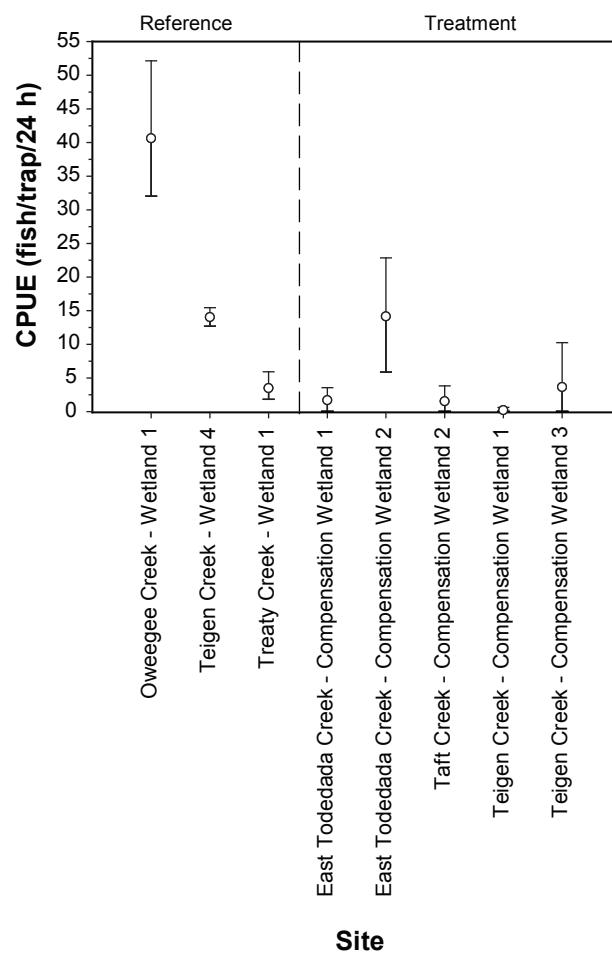

Appendix 7.4-4 presents species-specific biological data for wetland habitats. Appendix 7.4-5 presents a summary of descriptive statistics for standard and bootstrap fork length, weight and condition means. Comparisons of standard and bootstrap CPUE means indicate that the means are similar (< 0.01% difference) when sample size is greater than five; however, when sample size is less than five, the mean difference is greater (> 2% difference). Furthermore, the SD of bootstrapped means were similar to the SE of the standard mean when sample size was greater than five. Because replication was high, standard means are presented in illustrative comparisons.

The data collected represents the condition of late summer wetland rearing fish. Means were analysed using a one factor ANOVA testing for differences in mean between wetlands. Where transformation of data failed to meet assumptions of parametric ANOVA, a non-parametric Kruskal-Wallis or Mann-Whitney U test was used.

Mean fork length (Kruskal-Wallis, $H = 206.98, df = 6, P < 0.01$) and weight (Kruskal-Wallis, $H = 207.37, df = 6, P < 0.01$) of coho salmon were statistically significant between wetlands. Oweegee Creek Wetland 1 had a significantly lower mean fork length and weight than all other wetlands. These significant differences can be attributed to the abundance of fry sampled/present (Figures 7.4-5 to 7.4-7). There are significant differences in the condition (ANOVA, $F_{6,383} = 6.51, P < 0.001$) of sampled fish between wetlands (Figure 7.4-8). The condition of coho salmon in East Todedada Creek Wetland 2 was significantly lower than many other wetlands. Differences in condition could be attributed to local habitat conditions, population abundance and prey availability (Murphy and Willis 1996).

Mean fork length (ANOVA, $F_{4,107} = 15.77, P < 0.01$) and weight (ANOVA, $F_{4,106} = 9.28, P < 0.01$) of Dolly Varden were statistically significant between wetlands. Treaty Creek Wetland 7 had a significantly lower mean fork length and weight than all other wetlands. These significant differences can be attributed to the abundance of fry sampled/present (Figures 7.4-9 to 7.4-11). There are significant differences in condition (ANOVA, $F_{4,106} = 3.81, P < 0.01$) between wetlands (Figure 7.4-12). The condition of Dolly Varden in Teigen Creek Wetland 3 was significantly higher than Treaty Creek Wetland 4 and 7. Differences in condition could be attributed to local habitat conditions, population abundance and prey availability (Murphy and Willis 1996).

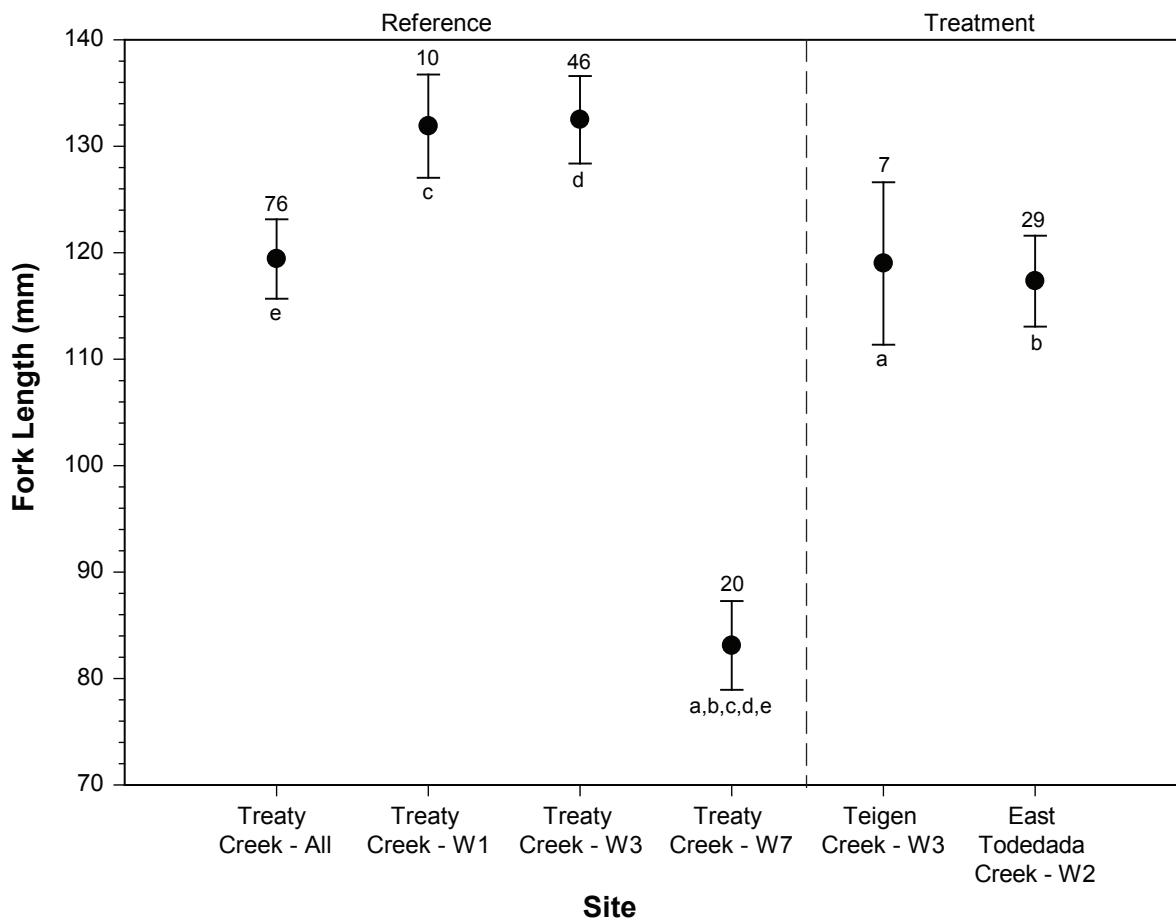

7.4.3.2 Growth

Appendix 7.4-4 presents species-specific biological data for wetland habitats. Appendix 7.4-6 presents a summary of descriptive statistics for standard and bootstrap mean ages. The SD of bootstrapped means were similar to the SE of the standard mean when sample size was greater than five. Since replication was high, standard means are presented in illustrative comparisons.

The data collected represents the growth of late summer wetland rearing Dolly Varden. Mean age (Kruskal-Wallis, $H = 24.99, df = 4, P < 0.01$) of Dolly Varden were statistically significant between wetlands. The mean age of Treaty Creek Wetland 7 was significantly lower than most of the other wetlands (Figure 7.4-13). The majority of Dolly Varden within the wetlands had a mean age of 3.5 years.

von Bertalanffy growth curves and a size-at-age linear regression was conducted for Dolly Varden in East Todedada Creek and Treaty Creek (Figures 7.4-14 to 7.4-16). The Akaike weights show the magnitude of support for each model; the model with the highest weight being the best fit model of three models compared. The fit of the all the von Bertalanffy growth models was poor given the narrow size range of the data, which is related to the short life expectancy of the species, and the lack of younger age classes present. Generally, the two-parameter (where t_0 is fixed at zero) von Bertalanffy growth model performed best compared to the three-parameter (or full) von Bertalanffy growth model because it predicted more realistic maximum (or asymptotic) fork lengths. However, the linear regression model performed better (almost twice as good) than the von Bertalanffy growth models.

8. Conclusion

8.1 OFF-CHANNEL HABITAT CREATION PROJECTS

The results of this study provide valuable insight into the feasibility and effectiveness of various sampling gear types and methods. The results provide an indication of gear bias and selectivity to sample life history stages of target fish species.

In 2011, streams selected for population abundance estimation were not conducive for mark-recapture or three-pass removal methods because habitat and flow conditions dictated that stop nets could not be utilized effectively. Stop nets could be used in East Todedada Creek, as attempted in 2011; however, only under low discharge conditions. The 2011 East Todedada Creek data was influenced by higher discharge and poor visibility during the recapture event.

The importance of multiple reference sites was highlighted in 2011, in which Treaty Creek Wetland 7 was lost/drained in August due to high flood events. In addition, Gilbert Creek reference stream sites were lost/ altered due to flood and channel migration events, which altered the stream morphology, water thermal regime, riparian community, discharge and resulting fish community.

8.2 INSTREAM HABITAT ENHANCEMENT PROJECTS

The results of stream enhancement compensation sites indicate that habitat cover is greater in target habitats than poor habitats. The results also indicate that the relative abundance is generally higher than poor habitat CPUE, and in certain cases is statistically significant. Biomass, density or total abundance cannot be calculated or compared between stream sites, except East Todedada Creek, due to the inability to enclose sites (i.e., three-pass depletion or mark-recapture methods) and differences in gear type between habitat types (i.e., electrofish and minnow trap). However, it is clearly apparent that biomass/density/abundance is higher in target habitats than poor habitat because minnow traps must be used in combination with electrofishing to effectively sample target pool habitats (i.e., parr and sub-adults are more abundant in pool habitat types).

Relative abundance data was variable between and within sites. The error associated with spatial variation in fish abundance/density within a stream (first stage error; Hankin 1984) is generally much greater than the measurement error in streams associated with estimating fish abundance at each site (second stage error). Stream fish populations are often highly clumped in their distribution as a result of spawning distribution (Beard and Carline 1991), geomorphic influences such as elevation, channel slope and stream size (Kruse et al. 1997), habitat variability, intercohort competition (Bohlin 1978), channel alterations (Elser 1968) or other factors. Research in streams has suggested that, as a result of high spatial variation in fish abundance, sampling a greater number of sites using a quicker but less precise method can provide greater precision in an abundance estimate overall for a given cost (Hankin and Reeves 1988; Decker et al. 1999). Hankin and Reeves (1988) recommended a strategy whereby a relatively quick method of population assessment, which is applied at a large number of sites, is calibrated to results from a more accurate but time-consuming method at a portion of the sites.

Each gear type was also biased in terms of size selectivity/capture. In all sites, the primary target life history stage and habitat is parr in pool habitats. The data demonstrated that minnow trapping was the most effective technique in sampling parr pool habitats. Oweegee Creek minnow trap CPUE was strongly influenced by high rain events during the sampling period; therefore, minnow trapping would have been more effective given seasonal normal discharge conditions. An analysis of the variation

2011 FISH AND FISH HABITAT COMPENSATION BASELINE REPORT

between electrofishing and minnow trap CPUE data indicates that minnow trap CPUE data has less variation in targeting parr. Minnow trapping is a relatively quick method of population assessment, which will be applied to a greater number of sites.

Turbidity:

C = clear

L = low turbidity

M = moderate turbidity

H = high turbidity

Dashes indicate not available in dataset

n = sample size

Enclosure:

O = open

C = closed

PE = partially enclosed

Dashes indicate not available in dataset

Species:

DV = dolly varden

RB = rainbow trout

CH = chinook salmon

BT = bull trout

CO = coho salmon

MWF = mountain whitefish

LSU = longnose sucker

			n	mean	SD	SE	Lower CI	Upper CI	Mean	SD	Lower CI	Upper CI
Reference	Oweegee Creek	Wetland 1	1	0.89	-	-	0.89	0.89	0.89	-	-	-
Reference	Teigen Creek	Wetland 4	1	0.96	-	-	0.96	0.96	0.96	-	-	-
Reference	Treaty Creek	Combined	76	0.89	0.08	0.01	0.75	1.04	0.89	0.01	0.88	0.91
Reference	Treaty Creek	Wetland 1	10	0.93	0.08	0.03	0.82	1.05	0.93	0.02	0.89	0.98
Reference	Treaty Creek	Wetland 3	46	0.89	0.07	0.01	0.76	1.01	0.89	0.01	0.87	0.91
Reference	Treaty Creek	Wetland 7	20	0.88	0.09	0.02	0.71	1.04	0.88	0.02	0.84	0.92
Treatment	East Todedada Creek	Wetland 2	28	0.91	0.05	0.01	0.84	1.02	0.91	0.01	0.90	0.93
Treatment	Taft Creek	Comp. Wetland 1	1	0.80	-	-	0.80	0.80	0.80	-	-	-
Treatment	Taft Creek	Comp. Wetland 2	1	0.88	-	-	0.88	0.88	0.88	-	-	-
Treatment	Teigen Creek	Comp. Wetland 3	7	0.99	0.08	0.03	0.90	1.08	0.99	0.03	0.94	1.04
Treatment	Treaty Creek	Comp. Wetland 1	3	0.91	0.05	0.03	0.86	0.96	0.92	0.02	0.86	0.96
Treatment	Treaty Creek	Comp. Wetland 2	1	1.01	-	-	1.01	1.01	1.01	-	-	-

Dashes indicate not applicable

SD = standard deviation of the mean

SE = standard error of the mean

n = sample size

CI = confidence interval (95%)
